Arterial oxygen saturation profiles in healthy preterm infants

A Ng, N Subhedar, R A Primhak, N J Shaw

Abstract

Aim—To construct a reference range of SpO₂ values in healthy preterm infants using a simple data logging device.

Methods—Thirty three healthy preterm infants were monitored for a continuous period of 4 hours at rest using an Ohmeda Biox 3700 E Pulse Oximeter and an electronic data logger (Rustrak Ranger). Stored data were downloaded and saved as individual files on a personal computer.

Results—The study group median and 5th and 95th percentiles were used to construct a cumulative frequency curve of time against SpO₂ value, representing the normal reference range of SpO₂ profiles in healthy preterm infants.

Conclusion—Comparison of an infant's SpO₂ profile against this curve may be more helpful in guiding supplemental oxygen treatment in that individual than a figure for a mean SpO₂ and its standard deviation.

Keywords: oxygen saturation; data logging device

Infants with chronic lung disease (CLD) are prone to major complications such as acute life threatening events¹ and pulmonary hypertension^{2,3} which may be related to chronic hypoxia.

In recent years monitoring of arterial oxygen saturation (SpO₂) using pulse oximetry has become the mainstay of assessment of oxygenation in preterm infants who have prolonged oxygen dependency.^{4,5} Although evaluation of the need for supplemental oxygen is invariably guided by measurements of SpO₂, there is currently no agreement as to what level of SpO₂ is acceptable in preterm infants with CLD. In the absence of any randomised trials comparing the safety and efficacy of different SpO₂ levels maintained by supplemental oxygen therapy, one approach is to aim for normal SpO₂ levels in these infants.^{6,7} There is, however, a lack of user friendly data on normal SpO₂ in healthy preterm infants.

Previous studies attempting to define a normal reference range of SpO₂ have used plethysmography and graphic analysis techniques.^{4,7} Although this methodology is undoubtedly meticulous, it is labour intensive and therefore impracticable for routine use in the neonatal nursery. Furthermore, data have been expressed as mean (SD) SpO₂ rather than as a distribution of SpO₂ values found with their relative frequencies of occurrence. A limitation of using most internal oximeter data storage

modes is that they involve intermittent sampling or averaging techniques which may lead to data being erroneously lowered by movement artefact. We have recently studied the usefulness of a data logging device to assess SpO₂ profiles. We describe our experience of using this system to collect data on SpO₂ profiles, to construct a simple reference range of SpO₂ values in healthy preterm infants.

Methods

Preterm infants who had received mechanical ventilation for less than six hours and supplemental oxygen for less than 48 hours were recruited after parental consent had been obtained. Infants with known congenital anomalies or cardiorespiratory disorders were excluded.

Demographic data were collected from maternal and infant case notes. Gestational age was assessed from maternal dates and/or early antenatal ultrasound examination. All infants were studied for a continuous period of four hours following a feed, while asleep, or during a period of quiet wakefulness. The infant was left undisturbed and the timing and duration of periods of activity (which may have led to signal artefact) were recorded separately by the nursing staff.

Arterial oxygen saturations and heart rate were continuously monitored using a Ohmeda Biox 3700e pulse oximeter with an averaging time of 3 seconds. The saturation probe was placed on the infant's hand or foot in a position that provided the most optimal signal.

An intelligent electronic datalogger (Rustrak Ranger, Outram Research, Bosham, UK) was connected to the analogue outputs for heart rate and saturation on the pulse oximeter. The logger was used in adaptive store mode, which has a sampling frequency of 2 Hz, but a storage frequency that varies continuously according to the remaining memory and the variability of the signal. This storage mode permits the accurate recording of rapid changes in saturation or heart rate, and enables movement artefact to be distinguished.

Stored data were downloaded from the Rustrak Ranger and saved as individual files on a personal computer. Each infant's files of SpO₂ and heart rate profiles were subsequently displayed in graphic form and analysed using dedicated software. After exclusion of obvious movement artefacts (defined as deflections to zero of both SpO₂ and heart rate tracings), analyses were performed in a standardised manner by the same observer (AN); this analysis involved calculation of: (1) the total duration of the recording; (2) overall mean

Figure 1

SpO₂; and (3) cumulative time (expressed as a percentage of total time) spent below a range of individual SpO₂ levels between 85 and 100%. Using the study group median and 5th and 95th percentiles, a cumulative frequency curve of time against SpO₂ level was then constructed. This represented the normal reference range of SpO₂ profiles in healthy preterm infants. Clinical staff were unaware of any of the results of the saturation studies.

Monitoring and analysis of SpO₂ profiles was then performed in a similar way in a well preterm infant in whom it was no longer felt that there was a clinical need for oxygen and in an infant with CLD who was receiving supplementary oxygen. Individual SpO₂ profiles were superimposed on the normal reference range to highlight any differences.

Results

Thirty three infants, 12 boys and 21 girls, were studied over a period of 7 months. Their median gestation was 33 (range 30–34) completed weeks and the median birthweight was 1798 (1020–2322) g. The median age at the time of study was 14 (range 2–28) days. No infant was receiving methylxanthines and all were breathing room air at the time of study. None had received a blood transfusion.

The median duration of monitoring (after exclusion of artefacts) was 240 (range 220–240) minutes. The median value of all the infants' mean SpO₂ values was 97% (range 92–100%). Figure 1 shows the graph of cumulative time against SpO₂ level for healthy preterm infants.

Examples of individual SpO₂ profiles are shown in figs 2 and 3.

Discussion

In this study we have constructed a reference range of normal SpO₂ distribution profiles in healthy preterm infants using a data logging device and dedicated software. The methodology used for analysing the data is relatively simple and practicable for routine use in the neonatal nursery.

The median of the mean SpO₂ levels reported in this study (97%) is lower than the baseline SpO₂ value of 99.5% cited in a previous study in which a Nellcor N200 pulse oximeter was used.⁴ Calculated levels of SpO₂ with the Ohmeda Biox III are about 2% lower than those obtained with the Nellcor N200, which may partly explain the discrepancy between the studies.⁸ If allowance is made for the different instruments used in the previous study, our results confirm that healthy preterm infants maintain relatively high baseline SpO₂ values. The consistency of this finding is particularly surprising given the marked differences in pulse oximeter setup and analysis of SpO₂ recordings in the two studies. Although we accept the desirability of detailed examinations of simultaneous SpO₂, heart rate, and respiratory tracings,^{4,7} particularly to detect acute cardiorespiratory events, we feel that this methodology cannot routinely be used and is not relevant when the main objective is to detect persistent mild hypoxia.

None of our infants had received a blood transfusion before the study. It is likely, therefore, that all infants had predominantly haemoglobin F (HbF) in their blood. As HbF has a greater affinity for oxygen than haemoglobin A (HbA), it could be argued that normal SpO₂ in our study infants could not be used to assess an older infant with predominantly HbA in their blood or one who had been transfused. However, previous studies in infants have suggested that the amount of HbF does not have a clinically significant effect on SpO₂.⁹

The cumulative frequency curve of oxygen saturations represents the range of SpO₂ profiles in normal preterm infants. This curve may be more helpful in guiding supplemental oxygen treatment in infants with CLD as it provides a more visual user friendly display of

the normal range of oxygen saturation than a single figure for a mean (SD) SpO₂ does. For example, monitoring an infant in whom it is thought that supplemental oxygen treatment may be required in air over a period of a few hours would permit the construction of an individual SpO₂ profile. By superimposing this individual profile on the group cumulative frequency curve, any deviation from the normal SpO₂ profile pattern could be assessed. If the infant's profile shifts to the left (with a greater proportion of time spent at SpO₂ levels below normal values), this might indicate a requirement for supplemental oxygen. The exact requirement could also be adjusted by repeating the process once the infant was receiving supplemental oxygen (as illustrated by the SpO₂ curve of the infant in fig 3). Oxygen saturation profiles could also be produced for older children to enable infants with CLD to be assessed for their oxygen requirement after discharge from the neonatal unit. Further studies are required to assess whether the decision to stop an infant's supplementary oxygen, based on clinical examination and routine observations of oxygen saturations in the neonatal nursery, correlates with a normal oxygen saturation profile; and whether deviation from the oxygen saturation profile in infants with previous CLD who are breathing room air is associated with a poorer outcome.

Infants in this study were monitored for a continuous period of four hours while undisturbed. Recording of SpO₂ levels during activities such as feeding and handling were not studied because of the potential inaccuracies related to movement artefact. Monitoring for a more prolonged period would inevitably have included such episodes, and would have required further detailed examination of SpO₂ tracings to exclude artefacts. Furthermore, state of wakefulness and feeding in themselves may affect SpO₂ values.⁷⁻¹⁰ Our aim in this

study was to develop a method of assessing SpO₂ profiles that was easy to use. Restricting the duration of recording to four hours permitted a reasonable period of study, while maintaining the practicability of the method. Although we excluded major movement artefact from the analysis, we cannot be certain that minor artefacts resulting in transient desaturation were detected. The most likely effect of including these events would have been to lower marginally the overall mean SpO₂.

In summary, we have described a convenient, relatively inexpensive, and easy to use system to obtain SpO₂ profiles in healthy preterm infants. Using this method we have constructed a normal reference range for SpO₂. Comparison of an individual's SpO₂ profile against these normal values may help to guide supplemental oxygen treatment in infants with CLD.
