The effects of a one-to-one nurse-to-patient ratio on the mortality rate in neonatal intensive care: a retrospective, longitudinal, population-based study

S I Watson, W Arulampalam, S Petrou, N Marlow, A S Morgan, ES Draper, N Modi. On behalf of the Neonatal Data Analysis Unit (NDAU) and the Neonatal Economic, Staffing, and Clinical Outcomes Project (NESCOP) Group

ABSTRACT

Objective To estimate the effect of the provision of a one-to-one nurse-to-patient ratio on mortality rates in neonatal intensive care units.

Design A population-based analysis of operational clinical data using an instrumental variable method.

Setting National Health Service neonatal units in England contributing data to the National Neonatal Research Database at the Neonatal Data Analysis Unit and participating in the Neonatal Economic, Staffing, and Clinical Outcomes Project.

Participants 43 tertiary-level neonatal units observed monthly over the period January 2008 to December 2012.

Intervention Proportion of neonatal intensive care days or proportion of intensive care admissions for which one-to-one nursing was provided.

Outcomes Monthly in-hospital intensive care mortality rate.

Results Over the study period, the provision of one-to-one nursing in tertiary neonatal units declined from a median of 9.1% of intensive care days in 2008 to 5.9% in 2012. A 10 percentage point decrease in the proportion of intensive care days on which one-to-one nursing was provided was associated with an increase in the in-hospital mortality rate of 0.6 (95% CI 1.2 to 0.0) deaths per 100 infants receiving neonatal intensive care per month compared with a median monthly mortality rate of 4.5 deaths per 100 infants per month. The results remained robust to sensitivity analyses that varied the estimation sample of units, the choice of instrumental variables, unit classification and the selection of control variables.

Conclusions Our study suggests that decreases in the provision of one-to-one nursing in tertiary-level neonatal intensive care units increase the in-hospital mortality rate.

INTRODUCTION

Nurse shortages are a continuing problem for healthcare both in the UK and elsewhere. Nurse-to-patient ratios have declined in hospitals across many areas of healthcare despite a number of studies providing evidence for an association between increased nurse-to-patient ratios and a reduction in adverse patient clinical outcomes.

A one-to-one nurse-to-patient ratio is recommended by the British Association of Perinatal Medicine (BAPM) for all infants receiving neonatal intensive care in the UK, with a ratio of 1:2 nurses recommended for infants receiving high dependency care and a ratio of 1:4 nurses for infants receiving special care. These levels of care are defined according to the care requirements of the infant, with intensive care requiring the most sustained support. Similar recommendations are provided by the American Academy of Pediatrics. Despite this, recent evidence shows that a large number of shifts in neonatal units are understaffed with respect to recommended nurse-to-patient ratios. Pillay et al found that 54% of nursing shifts in the six neonatal units they observed in England between October 2008 and February 2009 were understaffed with respect to the 2001 BAPM standards. In 2005, BAPM reported that only 26% of neonatal intensive care units (NICUs) met national staffing recommendations. Understaffing has also been reported in NICUs in the USA. This evidence has led some groups to advocate increased nurse staffing levels in neonatal units.
A recent systematic review of studies that examined nurse-to-patient ratios in neonatal clinical care settings identified six studies published between 1990 and 2010. As far as we are aware, only two further studies on this topic have been published since that time. The studies included in the systematic review estimated that higher nurse-to-patient ratios are associated with a reduction in risk-adjusted mortality, and of adverse events and nosocomial infection, and with an increase in daily weight gain. Of the identified studies, two were from the UK; results from these two studies, however, are based on the same data from 1998 to 1999, prior to wide, systematic changes in the structure of neonatal care in the UK from 2003 onwards. The authors of the systematic review concluded that the included studies were too heterogeneous to support any particular nurse-to-patient ratio. Moreover, these studies have not been able to observe specific nurse-to-patient ratios at the individual patient level nor adequately account for unobserved confounding that may occur due to higher-risk patients being more likely to receive more intensive nursing support. This in turn has limited the conclusions that can be made regarding the causal effects of the nurse-to-patient ratio on patient clinical outcomes.

This study was designed to estimate the effect of one-to-one nursing on the monthly mortality rate in tertiary-level neonatal units in England. We assess whether tertiary-level neonatal units—those designated to provide intensive care—that provide a greater proportion of intensive care days with one-to-one nursing have lower mortality rates using a novel statistical analysis to account for unobserved confounding.

**METHODS**

**Data source and study population**

Data were extracted from the National Neonatal Research Database (NNRD) for tertiary-level neonatal units participating in the Neonatal, Economic, Staffing, and Clinical Outcomes Project (NESCOP). We used self-reported unit classifications reported to the National Neonatal Audit Programme (NNAP) in 2010 to identify tertiary units. The NNRD comprises data extracted from the electronic patient records of all infants admitted to all 173 neonatal units in England with units joining the NNRD from 2006 onwards and not all units contributing in all years. NESCOP included 43 tertiary-level centres (of 165 centres overall) providing perinatal care that provided agreement for the inclusion of their data in the NNRD in 2011. NESCOP was able to use data from 30 tertiary units in 2008 (of 146 total units), 34 in 2009 (of 150), 41 in 2010 (of 164), 42 in 2011 (of 165) and 41 in 2012 (of 162). We extracted data on all infants who were admitted to a participating tertiary-level unit over the period 1 January 2008 to 31 December 2012. Two units changed classification during the study period. We, therefore, examined the robustness of our results to these classifications by additionally using unit classifications reported to NNAP in 2008 and 2012.

**Outcomes**

The data were aggregated to neonatal unit level by calendar month. Mortality data were derived from the extracted NNRD data. The outcome was specified as the monthly in-hospital intensive care mortality rate and specified as the number of deaths per 100 infants receiving intensive care per month in each neonatal unit.

**One-to-one nursing**

The NNRD records a binary variable indicating receipt of one-to-one nursing for each care day provided to each infant. We validated whether this variable represented whether an infant did receive, as opposed to should have received, one-to-one nursing on the indicated care day, by conducting a number of validation checks. First, we asked staff members at three different neonatal units what information they entered for this variable; second, we compared reported one-to-one nursing provision with clinical guidelines; third, we compared infant risk of mortality with one-to-one provision; and, fourth, we compared one-to-one nursing ratios with average nurse-to-patient ratios using data from a survey of neonatal units participating in NESCOP. The results of these validation checks are presented in online supplementary appendix A. For the analysis at neonatal unit level, the one-to-one nursing variable was specified in two ways: (1) the proportion of intensive care days on which one-to-one nursing was provided and (2) the proportion of infants receiving intensive care who were provided with at least one day of one-to-one nursing. Data were not available on cot numbers or overall staffing levels over the course of the study period.

**Covariates**

Following our previous work modelling mortality on neonatal units using NNRD data, and based upon a review of previous prediction models, we included a number of covariates in our statistical models that (a) were significant predictors of mortality, (b) were available in our data set and of high quality, and (c) not confounded by the provision of neonatal care. These were gestational age at birth, birth weight z-score (birth weight standardised by gestational age week), the monthly neonatal unit volume (to capture nurse workload) and the following indicators: whether the mother received a full or partial course of antenatal steroids, infant sex, infant year of birth (to capture trends in mortality over time) and calendar month (to capture any seasonal trends in mortality). In addition, a neonatal unit indicator (fixed effect) was included (see online supplementary appendix B).

**Statistical methods**

One-to-one nursing is assigned only to the sickest infants receiving neonatal intensive care, who will have the highest risk of mortality. This will generally lead us to underestimate the benefit or even to predict an adverse effect of one-to-one nursing due to the effect of unobserved confounding if infant health is not perfectly observed. We aggregated data to unit level for each calendar month in the sample so that unobserved heterogeneity at the infant level was not a confounding factor. A neonatal unit-level model was also arguably appropriate to inform neonatal unit-level policy. Nonetheless, there are two issues that may affect the analyses: (1) unoberved confounding at neonatal unit level and (2) reverse causality from the risk of mortality to one-to-one nursing due to the increased provision of intensive nursing to sicker infants (ie, ill health causing one-to-one provision).

A linear regression model was specified with controls for unobserved characteristics (unit fixed effects) to account for the neonatal unit-level unobserved confounding. The model was then estimated using ordinary least squares (OLS). To account for reverse causality, we used an instrumental variables estimator. This instrumental variables estimator involves the use of a variable, termed an ‘instrument’ that in this context fulfils two criteria: (1) it should be strongly correlated with the one-to-one nursing ratio in a particular month and (2) it should not be correlated with the outcome of interest conditional on observed covariates, including one-to-one nursing. For the instruments,
we used lagged values of the one-to-one nursing ratio (ie, previous months’ values for one-to-one nursing ratios for the respective neonatal unit) since (1) a particular month’s one-to-one nursing ratio should be correlated with previous monthly ratios at a unit level given the availability of nursing staff and local nursing practices and (2) the previous monthly ratios should be uncorrelated with unobserved confounders during the month of analysis. The number of lagged values included was determined by sequential testing (see online supplementary appendix B). To test the first condition, we conducted an F-test for the significance of the lagged values, and to test the second condition we conducted a Hansen J test. The SEs were adjusted for clustering within units. Analyses were conducted in Stata V.12.

Sensitivity analyses
A number of sensitivity analyses were conducted to determine the robustness of the results to the statistical methods, the set of included covariates and assumptions of the models. In particular, we tested the sensitivity of our results to (1) including only neonatal units that provided data for all months of the analysis; (2) exclusion of any outlying units identified from a graphical inspection of the data; (3) inclusion of non-tertiary units that provide an average monthly level of intensive care at least as large as the smallest tertiary unit; (4) re-estimating the models with no covariates, except for unit-level indicators and the one-to-one nursing variable; (5) using a different number of lagged values for the instruments; (6) using 2008 and 2012 reported unit classifications; and (7) removing data from 2008 when large decreases in one-to-one nursing were observed that were not observed in subsequent years.

RESULTS
Summary statistics
Overall, data from 43 unique tertiary neonatal units were included in our primary analyses. Of the remaining 122 neonatal units in NESCoP 82 reported as being level 2 and 40 as level 1 in 2010. Table 1 shows summary statistics for the sample; the top panel shows sample aggregate statistics, while the lower panel shows neonatal unit median values. The median annual proportion of intensive care days on which one-to-one nursing was provided in tertiary neonatal units in the sample declined from 9.1% in 2008 to 5.9% in 2012. Similarly, the proportion of infants admitted to intensive care receiving any one-to-one nursing during their care declined from 39.4% to 35.7% over the same period. The median (IQR) in-hospital intensive care mortality rate was 4.5 (0.0 to 8.3) deaths per 100 infants receiving intensive care per month.

Regression results
Estimated effects of one-to-one nursing on the in-hospital intensive care mortality rate are reported in table 2 for both OLS and the instrumental variables estimator. The OLS results revealed a positive association between the one-to-one nursing ratio and the in-hospital intensive care mortality rate, suggesting that a 10 percentage point decrease in the proportion of intensive care days on which one-to-one nursing was provided was associated with a decrease in the mortality rate of 0.6 deaths per 100 infants receiving intensive care per month (95% CI −1.2 to −0.0). Where one-to-one nursing was measured as the proportion of infants who received at least one day of one-to-one nursing care, a 10 percentage point decrease in one-to-one nursing led to an increase of 0.4 deaths per 100 infants receiving neonatal intensive care per month (95% CI −0.7 to −0.0).

Sensitivity analyses
The results from the sensitivity analyses are presented in online supplementary appendix C, tables C1–C4. In all cases, the estimated coefficients were negative and were qualitatively similar to the main results. Removal of neonatal units that did not contribute data in all months of the analysis and removal of one outlying unit generally resulted in an increase in the magnitude of the estimated coefficients while reducing precision of the estimates (see online supplementary tables C1 and C3). Varying the lag length of the instrumental variables used had small effects on the magnitude of the estimated coefficients of interest and SEs as was expected (see online supplementary tables C2 and C4). For one-to-one nursing measured as a proportion of intensive care days, the inclusion of extra lagged months as instrumental variables had little qualitative effect on the estimated coefficient, while reducing the number of lagged months reduced the magnitude of the coefficient. For one-to-one nursing measured as a proportion of admissions, the inclusion of extra lagged months increased the magnitude of the estimated coefficient, while reducing the number of lagged months had little qualitative effect on the estimated coefficient. The choice of lag length used as instrumental variables, therefore, affects the point estimates of the effect of one-to-one nursing, suggesting there is a fair amount of uncertainty about the effects of one-to-one nursing on the mortality rate; however, these changes did not affect the general conclusions drawn from the results that an increase in the provision of one-to-one nursing was associated with a reduction in the mortality rate. Variations in reported unit classifications over the study period did not affect the results. Removal of data from 2008, given the trend observed in this period, did not affect the magnitude of the estimate but did reduce its precision.

DISCUSSION
We examined the effect of one-to-one nursing in neonatal intensive care on the monthly mortality rate in NICUs for infants admitted to neonatal units in England. The key finding was an increase in the mortality rate in tertiary-level neonatal units when a decreased proportion of intensive care days was provided with one-to-one nursing. The results from the OLS results showed the opposite effect, which provides evidence that sicker infants were more likely to be provided with one-to-one nursing, thereby confounding the standard analysis. The results from analyses where an alternative measure of one-to-one nursing, along with the results from a wide variety of robustness checks, were all qualitatively similar, supporting the main instrumental variables estimator findings.

The methods used in this study enabled us to account for a number of sources of unobserved confounding so that our results can be arguably interpreted as causal effects in the absence of a randomly assigned one-to-one nurse-to-patient ratio. This study employed an instrumental variable method, which has been widely applied in other healthcare evaluations. However, we are only aware of two previous studies incorporating this method in perinatal settings, including one study using NNRRD data previously conducted by the authors. Our
findings can be compared with three previously conducted studies that found a reduction in risk-adjusted mortality with higher nurse-to-patient ratios in neonatal healthcare. One previous study did find an increase in mortality. However, none of the cited earlier studies took into account the various sources of unobserved confounding and the possibility of reverse causality, and all examined the effects of an average nurse-to-patient ratio in cross-sectional contexts at the baby level without being able to examine within-unit changes to nurse-to-patient ratios over time. The difference between our OLS and instrumental variables estimator results suggest that there is significant reverse causality from one-to-one nursing to mortality, which may be caused by unobservable differences in patient case mix or by differences or changes over time to the technology in use by neonatal units.

The results presented in this study could serve as inputs into models that estimate the incremental cost per life saved associated with increased provision of one-to-one nursing. As an illustrative example of this, consider the case of a hospital providing 180 intensive care days per month. If it is assumed that infants who receive intensive care at a ratio of 2:1 rather than 1:1, then an increase in the one-to-one nursing rate of 10 percentage points requires an additional nine days of nursing labour, which would have the effect of reducing the mortality rate by 0.6 percentage points, equivalent to 1.08 deaths. The unit costs for an hour of face-to-face specialist nursing was estimated at £64 in 2014. This would result in an incremental cost of £12,800 per life saved, which would generally be considered cost-effective by decision-making bodies such as the National Institute for Health and Care Excellence in England and Wales. We recognise that this calculation is illustrative rather than proscriptive, and further research is required to incorporate considerations of staff position, qualifications, experience and other factors.

We acknowledge limitations to our study. Our study is only able to identify the ‘marginal’ effects of the one-to-one nursing ratio on the in-hospital intensive care mortality rate; the effects of large increases in one-to-one nursing provision remain unknown. Even with 100% one-to-one nursing provision to infants during neonatal intensive care, the mortality rate will not be zero. Thus, while these findings support an increase in one-to-one nursing provision on tertiary-level neonatal units, they do not inform us whether a one-to-one nurse-to-patient ratio for all intensive care days would have a beneficial effect. We are, furthermore, not able to identify the optimal nurse-to-patient ratio given that we only observe whether an infant received one-to-one nursing or not; for example, it is possible that a greater than one-to-one nurse-to-patient ratio has additional beneficial effects. Further research is required to determine the optimal levels of nurse staffing to best improve infant clinical outcomes. This would involve infant-level, daily observations of nursing support for infants receiving care in a neonatal unit.

One further weakness of our study is that we are not able to determine whether nurses should be reallocated from other nursing tasks in neonatal units to one-to-one nursing in neonatal intensive care. Time-use studies were conducted in the early 1990s to determine nurse-to-patient ratios recommended by BAPM. A more recent study reaffirmed these results and suggested required nursing time had increased. New time-use studies are, therefore, an important area for future research.

Our study is also not able to suggest when during an infants’ care one-to-one nursing would achieve its optimal effects. Increasing one-to-one nursing provision is assumed to reduce preventable nursing errors that may lead to mortality. In the first hours of life, this effect may be small as the underlying medical condition may have a larger effect. Many errors may not be prevented by increasing the nurse-to-patient ratio but through other quality improvements. We have assumed that increases in the provision of one-to-one nurses are indicative of increases in the overall nurse-to-patient ratio. Nevertheless, we have provided evidence that increases in one-to-one nursing provision for neonatal intensive care lead to a reduction in mortality. Further research is required both to establish how this is achieved in practice and to find other quality improvements that may reduce mortality. We also note that given the complexities
This study provides evidence to support the claim that tertiary-level neonatal units with higher levels of one-to-one nursing provision have reduced mortality rates. Further research is clearly warranted on the best way to achieve this. Furthermore, the benefits of increasing the nurse-to-patient ratio may be underestimated in this study since common neonatal morbidities are not considered, and previous studies have shown an increased nurse-to-patient ratio is associated with a reduction in the risk of diseases such as infection, bronchopulmonary dysplasia and intraventricular haemorrhage. This would be an important extension to these analyses in future. We believe the results in this study provide some evidence in support of a one-to-one nurse-to-patient ratio in neonatal intensive care in England, in line with BAPM guidelines, and therefore provide evidence in support of increased nursing labour provision on neonatal units in England.

Results are presented from two different estimators: (1) ordinary least squares, which does not control for the correlation between the one-to-one nursing and unobserved case-mix differences; (2) instrumental variables estimator, which does control for the correlation between the one-to-one nursing and unobserved case-mix differences using historical nursing levels. Results are interpreted as change in the number of deaths per 100 infants receiving neonatal intensive care per month resulting from a 10 percentage point increase in one-to-one nursing. Regressions control for the mean values of gestational age, birth weight z-score, antenatal steroid receipt and gender, as well as year, calendar month and neonatal unit effects (see online supplementary appendix B). The number of observations are fewer for the instrumental variables estimation as lagged variables are used as instruments. Sensitivity analyses are presented in online supplementary appendix C.

Fall in one-to-one nursing care of very sick newborns linked to higher death rate

Provision fell by around a third in England between 2008 and 2012

A fall in the provision of one to one nursing care of very sick and premature newborns is linked to a higher death rate in neonatal intensive care, finds research published online in the *Archives of Disease in Childhood (Fetal & Neonatal Edition)*.

The proportion of this type of nursing care provided in neonatal intensive care units fell by around a third between 2008 and 2012, the findings show.

The British Association of Perinatal Medicine (BAPM) recommends one to one nursing care for newborns in neonatal intensive care in the UK, and a ratio of one nurse for every two infants in high dependency units. For infants in receipt of special care, the recommended ratio is 1:4.

Yet few neonatal units have achieved the required staffing ratios.

The researchers wanted to assess the impact of one to one nursing on the monthly death rate in tertiary level neonatal units—those designated to provide intensive care—in England.

They therefore extracted monthly data supplied to the National Neonatal Research Database on infants admitted to 43 tertiary level care units between 2008 and 2012.

Using these figures, they calculated the proportion of neonatal intensive care days or intensive care admissions for which one to one nursing care was provided during this timeframe.

Between 2008 and 2012, the proportion of one to one nursing care provided in tertiary level neonatal units fell by a third, from an average of 9% to an average of around 6%.

Similarly, the proportion of infants admitted who received one to one nursing care fell from around 39.5% to just under 36%.

During this period, an average of 4.5 infants out of every 100 (4.5%) in receipt of intensive care, died every month.

The researchers calculated that a 10 percentage point fall in the proportion of intensive care days on which one to one nursing care was provided was associated with a monthly increase in the inpatient death rate of 0.6 per 100 infants (0.6%) in intensive care.

This is an observational study so no firm conclusions can be drawn about cause and effect, and sicker infants are more likely to be provided with one to one nursing care, so are at greater risk of death to start with.

“While these findings support an increase in one to one nursing provision in tertiary level neonatal units, they do not inform us whether a one to one nurse to patient ratio for all intensive care days would have a beneficial effect,” the researchers caution.

Nevertheless, they conclude: “We believe the results in this study provide some evidence in support of a one to one nurse to patient ratio in neonatal intensive care in England, in line
with BAPM guidelines, and therefore provide increased nursing labour provision on neonatal units in England."

In a linked editorial, Dr Alan Fenton, Sue Turrill, and Caroline Davey, the chief executive of premature and sick baby charity Bliss, point out that over 90,000 babies were admitted to neonatal units in England, Scotland, and Wales in 2014: just under 14% of the care days these babies received was in intensive care.

They highlight the health secretary’s ambition, announced at the end of last year, to cut the rate of stillbirths, neonatal and maternal deaths in England by 30% by 2030.

Laudable though this might be, “the announcement has so far singularly failed to acknowledge the importance of improving staffing levels in order to reduce neonatal deaths, despite consistent information from neonatal professionals," they write.

And recent government policy may worsen shortages, they suggest.

“While the Secretary of State has acknowledged the mistake made by the coalition government in 2010, in cutting the number of student nurse places commissioned, it is still far from clear whether the government’s plans to replace student nurse bursaries with loans, as outlined in the 2015 Comprehensive Spending Review, will have the desired effect of increasing the number of nurses trained, or will just put a barrier in the way of those who wish to join the profession,” they conclude.
Web Appendix C: Additional Results

In this appendix we present the results from the sensitivity analyses conducted for this study, all results in this section are from the instrumental variables estimator. Tables C1 and C2 present the results from the sensitivity analyses where the one to one nursing rate is measured as a percentage of care days. Tables C3 and C4 present the results from the sensitivity analyses where the one to one nursing rate is measured as the percentage of intensive care admissions who received at least one day of one to one care. All analyses, except where indicated, control for the mean values of gestational age, birth weight z-score, antenatal steroid receipt, gender, and monthly volume of intensive care as well as year and calendar month and neonatal unit indicator.

We conducted a number of analyses to examine the sensitivity of the results to various possible misspecifications and issues of sample selection bias – discrepancies between the estimated effect in these analyses and those in the primary analysis presented in the main paper may indicate the presence of bias in the estimator.

To explore whether the observed effect was being driven by those units joining later in the sample we re-estimated the model using a balanced panel, i.e. using only those units that appeared in each month of the panel (tables C1 and C3, column (1)). We removed outlying units identified by graphical analysis (one unit had apparently high levels of one to one nursing in 2008, we also removed 2008 data as a sensitivity analysis, see below) (table C1 and C3, column (2)). Our primary sample comprised tertiary neonatal units, since these units are those which are designated to provide intensive care and hence one to one nursing; however, since some non-tertiary units may also provide a large amount of neonatal intensive care, we include these units as a sensitivity analysis (tables C1 and C3, column (3)). We also estimate a model with no covariates except for neonatal unit indicators and the one to one variable (tables C1 and C3, column (4)). A large discrepancy between this ‘crude’ model and the main results may indicate that the instrumental variable estimator is invalid since the instrumental variables may then be correlated with infant health. For the primary analysis we utilised unit classifications reported to NNAP in 2010, however, two neonatal units changed their classification during the course of the sample. We therefore examine the robustness of our results to using unit classifications reported to NNAP in 2008 and 2012 (tables C1 and C3, columns (5) and (6)). Table 1 in the main paper showed that one to one nursing rates appear significantly higher in 2008 than the other years in the sample; we therefore removed data from 2008 to see if these data were driving our results (tables C1 and C3, column (7)). Finally, we explored the effects of using different lags as instrumental variables (tables C2 and C4).
Table C1 Results from sensitivity analyses examining the effect of different samples of units and removing covariates from the model.

One to one nursing is measured as the percentage of intensive care days on which one to one nursing was provided. Results are interpreted as the change in the number of deaths per 100 infants receiving neonatal intensive care per month resulting from a ten percentage point increase in one to one nursing. Regressions control for the mean values of gestational age, birth weight z-score, antenatal steroid receipt, and gender as well as year, calendar month, and neonatal unit effects (Appendix B).

Balanced panel: only neonatal units for which data were available in all months of the sample. Removal of outlying unit: one unit was identified as being an outlier from a graphical analysis of the data. Inclusion of high intensive care volume units: any neonatal unit providing a volume of neonatal care at least as great as the lowest volume tertiary unit in addition to tertiary level units. No covariates: crude model containing only neonatal unit effects and one to one nursing variables. 2008/2012 unit classifications: using neonatal unit levels reported to NNAP in the respective years. 2008 observations excluded: removal of 2008 data during which a large decrease in one to one nursing rates were observed which was not observed in subsequent years.

Fall in one-to-one nursing care of very sick newborns linked to higher death rate

Provision fell by around a third in England between 2008 and 2012

A fall in the provision of one to one nursing care of very sick and premature newborns is linked to a higher death rate in neonatal intensive care, finds research published online in the Archives of Disease in Childhood (Fetal & Neonatal Edition).

The proportion of this type of nursing care provided in neonatal intensive care units fell by around a third between 2008 and 2012, the findings show.

The British Association of Perinatal Medicine (BAPM) recommends one to one nursing care for newborns in neonatal intensive care in the UK, and a ratio of one nurse for every two infants in high dependency units. For infants in receipt of special care, the recommended ratio is 1:4.

Yet few neonatal units have achieved the required staffing ratios.

The researchers wanted to assess the impact of one to one nursing on the monthly death rate in tertiary level neonatal units—those designated to provide intensive care—in England.

They therefore extracted monthly data supplied to the National Neonatal Research Database on infants admitted to 43 tertiary level care units between 2008 and 2012.

Using these figures, they calculated the proportion of neonatal intensive care days or intensive care admissions for which one to one nursing care was provided during this timeframe.

Between 2008 and 2012, the proportion of one to one nursing care provided in tertiary level neonatal units fell by a third, from an average of 9% to an average of around 6%.

Similarly, the proportion of infants admitted who received one to one nursing care fell from around 39.5% to just under 36%.

During this period, an average of 4.5 infants out of every 100 (4.5%) in receipt of intensive care, died every month.

The researchers calculated that a 10 percentage point fall in the proportion of intensive care days on which one to one nursing care was provided was associated with a monthly increase in the inpatient death rate of 0.6 per 100 infants (0.6%) in intensive care.

This is an observational study so no firm conclusions can be drawn about cause and effect, and sicker infants are more likely to be provided with one to one nursing care, so are at greater risk of death to start with.

“While these findings support an increase in one to one nursing provision in tertiary level neonatal units, they do not inform us whether a one to one nurse to patient ratio for all intensive care days would have a beneficial effect,” the researchers caution.

Nevertheless, they conclude: “We believe the results in this study provide some evidence in support of a one to one nurse to patient ratio in neonatal intensive care in England, in line
with BAPM guidelines, and therefore provide increased nursing labour provision on neonatal units in England."

In a linked editorial, Dr Alan Fenton, Sue Turrill, and Caroline Davey, the chief executive of premature and sick baby charity Bliss, point out that over 90,000 babies were admitted to neonatal units in England, Scotland, and Wales in 2014: just under 14% of the care days these babies received was in intensive care.

They highlight the health secretary’s ambition, announced at the end of last year, to cut the rate of stillbirths, neonatal and maternal deaths in England by 30% by 2030.

Laudable though this might be, “the announcement has so far singularly failed to acknowledge the importance of improving staffing levels in order to reduce neonatal deaths, despite consistent information from neonatal professionals,” they write.

And recent government policy may worsen shortages, they suggest.

“While the Secretary of State has acknowledged the mistake made by the coalition government in 2010, in cutting the number of student nurse places commissioned, it is still far from clear whether the government’s plans to replace student nurse bursaries with loans, as outlined in the 2015 Comprehensive Spending Review, will have the desired effect of increasing the number of nurses trained, or will just put a barrier in the way of those who wish to join the profession,” they conclude.
