Low birthweight infants and total parenteral nutrition immediately after birth. III. Randomised study of energy substrate utilisation, nitrogen balance, and carbon dioxide production

J S Forsyth, N Murdock, A Crighton

Abstract
This study aimed to investigate energy substrate utilisation and nitrogen balance in low birthweight infants receiving total parenteral nutrition during the first days of life, and in particular, to determine the effect of two different glucose intakes on carbon dioxide production. Twenty infants (mean (SE) birthweight 1314 (65) g, mean (SE) gestation 30-9 (0-4) weeks) were recruited to the study. Immediately after birth they were randomised to a carbohydrate intake of 8 g/kg/day (5-5 mg/kg/minute) or 12 g/kg/day (8-3 mg/kg/minute). After 24 hours they were changed to the alternative regimen which was continued for a further 24 hours. Fat and protein intakes were kept constant throughout the study. Indirect calorimetry was performed during each of the regimens, urine was collected for urinary nitrogen, and substrate utilisation calculated for 12 infants.

The carbohydrate utilisation rate was increased during the higher carbohydrate intake. Lipid utilisation rates were significantly different, with net lipid synthesis occurring during high carbohydrate intake. Protein utilisation rates were not influenced by the different carbohydrate intakes. The mean plasma glucose concentration was higher during the high carbohydrate intake but the mean highest and lowest values were not significantly different during the two study periods. A plasma glucose below 2-6 mmol/l was recorded more frequently during the low glucose intake (9/20 v 5/20). Capillary Pco2 values measured during high and low glucose intakes were similar (5-9 (0-2) v 6-2 (0-3) kPa. Carbon dioxide production rates were increased during the higher carbohydrate intake but the differences were not significant. Similarly, there was no significant difference in the respiratory quotients (RQ), oxygen consumption, or energy expenditure during the two study periods.

Keywords: total parenteral nutrition, low birthweight infant, nitrogen balance, oxygen consumption.

It is common practice for preterm infants requiring nutritional support to be gradually started on parenteral nutrition over a period of several days. Consequently, the infant is in negative energy and nitrogen balance during the immediate postnatal period. It is at this time that infants are frequently most sick and in need of optimal nutrition. In an extensive review of parenteral nutrition the lack of evidence to support this practice was highlighted, and in particular, the view that infants were unable to tolerate more than maintenance amounts of amino acids during the immediate neonatal period was questioned. Although there is now evidence that amino acid solutions and fat emulsions administered separately can be tolerated by low birthweight infants during the first days of life, nutritional requirements at this time remain uncertain because of the lack of energy and nitrogen balance studies performed immediately after birth in parenterally fed low birthweight infants.

Data from studies in adults and one study in preterm infants demonstrate that an intake of glucose above energy requirements results in synthesis of new fat from excess carbohydrate, and that this process significantly increases carbon dioxide production. This may necessitate an increase in minute ventilation and may compromise respiratory function in a susceptible infant. The respiratory quotient (RQ), which is the ratio of carbon dioxide production to oxygen consumption, is greater than 1-0 in those circumstances. We have reported before that during the first days of life when glucose is the sole energy source and respiratory disease is most prevalent, infants frequently have an RQ in excess of 1-0. Inappropriate glucose intakes may be exacerbating the severity of respiratory disease in these infants.

Methods
Twenty infants (mean (SE) birthweight 1314 (65) g, mean (SE) gestation 30-9 (0-4) weeks) were recruited to the study after informed consent had been obtained from parents or guardians. Three infants were receiving artificial ventilation and the remainder were breathing air spontaneously. Immediately after birth they were randomly allocated to a carbohydrate intake of 8 g/kg/day (5-5 mg/kg/minute) or 12 g/kg/day (8-3 mg/kg/minute). After 24 hours they were changed to the alternative regimen which was continued for a further 24 hours. Fat and protein intakes were kept constant throughout the study (table 1).

Values: means (SE).

Indirect calorimetry was performed, using methods described before, for a minimum period of 120 minutes during each study period, and urine was collected for measurement of urinary nitrogen. Substrate utilisation was calculated using the equations described by Consolazio.

Blood gas analysis and blood glucose measurements were performed during the study periods. The infants were nursed in an open intensive care bed or an incubator which provided a thermo-neutral environment. The parenteral fluids were infused through neonatal infusion pumps and volumes were accurately recorded. The study was designed so that the infant would be minimally inconvenienced and routine nursing and clinical procedures could proceed unhindered.

The experimental design was a Latin square crossover in which each infant served as his or her own control. This design permitted the evaluation of the effect of high or low glucose intake, the effect of time (for example, day 1 vs day 2), and the effect of order of administration of regimens. The effect of high versus low carbohydrate intake was analysed using the following outcome measures: carbohydrate, fat, and protein utilisation rates; and carbon dioxide production rates. The outcomes were compared using ANOVA and paired t tests.

Results
The actual nutrient intakes received by the infants during the two study periods are shown in table 1. Carbon dioxide rates were increased during the higher carbohydrate intake but the differences were not significant. Similarly, there was no significant difference in the RQs, oxygen consumption, or energy expenditure during the two study periods (table 2). Adequate paired urine collections for urinary nitrogen measurements were obtained in 12 infants and nutrient utilisation was calculated for these infants (table 3). The carbohydrate utilisation rate was increased during the higher carbohydrate intake. Lipid utilisation rates were significantly different, with net lipid synthesis occurring during high carbohydrate intake. Protein utilisation rates were not influenced by the different carbohydrate intakes. Nutrient utilisation rates were not altered by order of administration of regimens or the time of administration (table 4).

The mean plasma glucose concentration was higher during the high carbohydrate intake but the mean highest and lowest values were not significant during the two study periods (table 5). A plasma glucose below 2.6 mmol/l was recorded more frequently during the low glucose intake (9/20 v 5/20). Capillary Pco2 values measured during high and low glucose intakes were similar (5.9 (0.2) v 6.2 (0.3) kPa).

Discussion
This study provides substrate utilisation data for low birthweight infants receiving total parenteral nutrition during the first 48 hours of life. Two parenteral regimens, differing in glucose content but with similar lipid (1.8 kg/kg/day) and nitrogen content (1.5 kg/kg/day), were evaluated. The glucose content of the regimens was based on that frequently administered during the first two days of life (8 kg/kg/day) and that which would be required to maintain a positive energy balance according to recent energy expenditure data (12 kg/kg/day). The amino acid and lipid composition was based on recent biochemical tolerance studies. This study shows that a positive energy and nitrogen balance can be achieved immediately after birth with a mix of energy substrates which will not significantly disturb glucose homeostasis or respiratory gas exchange.

During the higher glucose intake, glucose utilisation and retention were increased. Retention during the low glucose regimen was minimal, the intake barely meeting the utilisation demands. These data agree with those of previous studies which have shown that glucose utilisation is directly related to glucose intake. Glucose utilisation rate is a measure of the disappearance rate of glucose and does not distinguish between glucose which is being oxidised directly and glucose which is being converted into fat. Excess glucose is converted to fat when the maximal glucose oxidative rate has been reached. If the non-protein RQ is greater than 1.0, fat oxidation rate assumes a negative value, indicating that there is net fat synthesis— that is, total fat oxidation minus fat synthesised from

During lipogenesis there is a substantial increase in carbon dioxide production.
Healthy adults compensate for the increased carbon dioxide production by increasing minute ventilation, but in patients with respiratory disease, hypercapnia necessitating increased ventilation has been described. In one previous study involving preterm infants aged 5–21 days, the infants receiving high glucose loads (15 g/kg/day) had significantly increased rates of carbon dioxide production, RQs, transcutaneous PCO2 and alveolar minute ventilation compared with infants receiving lower glucose intakes (10 g/kg/day). In our study in which the glucose intakes were lower, carbon dioxide production was increased during the high carbohydrate intake but the difference was not significant. The mean RQ for both regimens was 1-0 or less. Measurements of respiratory function were not performed in our study but PCO2 values measured at the beginning and the end of each trial regimen did not significantly differ, suggesting that the mild increase in carbon dioxide production during the higher glucose intake did not compromise respiratory function.

The plasma glucose values were higher during the high carbohydrate regimen but remained within normal limits. Fewer infants on this regimen experienced a plasma glucose of less than 2-6 mmol/l.

Protein utilisation was not significantly influenced by varying glucose intake and a moderate nitrogen retention was achieved during both regimens. An early study showed that low birthweight infants who were starved during the first days of life catabolised body protein stores at a rate of 1 g/kg/day, although this can be partially reversed by the provision of glucose, infants receiving parenteral feeding regimens that are devoid of amino acids will remain in negative nitrogen balance. If amino acids are provided positive nitrogen retention can be achieved even in the presence of energy intakes as low as 35 kcal/kg/day. Further increases in nitrogen retention can be obtained by enhancing energy intake, but once this has exceeded 70 kcal/kg/day, the actual intake of nitrogen becomes the major determinant of nitrogen retention. As protein retention rates in our study were lower than intrauterine retention rates of similar gestational age, and the energy intake in the high glucose regimen was 75 kcal/kg/day, an increase in amino acid intake would be required to enhance further nitrogen retention at this time.

We are currently no formal guidelines on energy and nutrient intakes for sick preterm infants. The ESPGAN guidelines for the nutritional requirements of preterm infants make no specific recommendations for the nutritional management of infants fed by the parenteral route. From our study of infants who were considered to be sufficiently unwell not to tolerate enteral feeds, the administration immediately after birth of a parenteral regimen consisting of glucose 10–12 g/kg/day, and amino acids 1–2 g/kg/day, and lipid 1–2 g/kg/day will meet energy and protein requirements for maintenance and continuing growth.
