Measurement of carbon dioxide production in very low birth weight babies

C C Kingdon, F Mitchell, O A F Bodamer, A F Williams

Abstract

Background—CO₂ production is most commonly measured by using indirect calorimetry to quantify elimination of CO₂ in breath (VCO₂). An alternative is to measure the rate at which CO₂ appears in the body pool (Raco₂) by infusing a 13C labelled bicarbonate tracer. VCO₂ and Raco₂ generally differ but are related by c, a factor that adjusts for the incomplete recovery of infused tracer in the breath. The literature relating to human studies cites a wide range of values for c but the only neonatal study to determine c empirically estimated a mean value of 0.77.

Aim—To estimate fractional recovery rate, c, in very low birthweight babies, and assess the feasibility of using the isotopic technique to measure CO₂ production during mechanical ventilation.

Method—Eleven spontaneously breathing, continuously fed, very low birthweight infants (median birth weight 1060 g, median gestational age 29 weeks) were studied.

Results—Mean (SD) VCO₂ was 9.0 (2.0) ml/min (standard temperature and pressure dry, STPD) and mean (SD) Raco₂ was 9.6 (2.1) ml/min (STPD). The mean (SD) value of c was estimated as 0.95 (0.13). The 95% confidence intervals of the mean were 0.87–1.03.

Conclusions—The results emphasise the importance of measuring c for a given study population rather than assuming a value based on adult studies. The close approximation of Raco₂ and VCO₂ in this group of babies implies that the labelled bicarbonate infusion technique could be used to measure simply CO₂ production during mechanical ventilation.

Keywords: carbon dioxide; carbon isotopes; calorimetry; very low birthweight babies

The measurement of CO₂ production has important clinical applications in the management of very small babies. If O₂ consumption is measured simultaneously, respiratory quotient can be calculated, allowing total energy expenditure and nature of fuel oxidised to be deduced. Potentially this could help in the choice of more appropriate nutritional interventions for infants who show constrained capacity to eliminate CO₂ because of lung disease. Measuring CO₂ production is especially problematical in ventilated very low birthweight (VLBW) infants. Conventionally, breath CO₂ elimination (VCO₂) is calculated by measuring gas flow and the CO₂ content of inspired and expired breath. This technique, indirect calorimetry, is subject to both technical errors, such as leakage of expired gas, and confounding by changes in minute ventilation. An alternative approach is measurement of the rate at which CO₂ produced by metabolism appears in the body bicarbonate pool (Raco₂, rate of appearance). This can be accomplished by measuring the isotopic enrichment (ratio of 13C to 12C) of CO₂ in expired breath while continuously infusing a 13C labelled sodium bicarbonate tracer at a known rate.

Studies of animals and adult humans have consistently shown that VCO₂ and Raco₂ differ. The discrepancy is principally attributable to incomplete recovery of 13C labelled CO₂ in breath when there is insufficient time for the infused label to equilibrate between body bicarbonate pools. A correction factor (c), given by the quotient of VCO₂ and Raco₂, can be used to adjust for the fractional recovery of tracer. The literature cites mean values of c ranging between 0.5 and 1.06 in different patient groups, and a value of 0.80 is often assumed in studies of substrate oxidation. A single published study of neonates yielded a mean (SD) estimate of 0.77 (0.05) but included only three babies weighing < 1500 g.

In view of the potential importance of accurately quantifying CO₂ production in VLBW babies and uncertainty about the magnitude of c in this group, we have simultaneously measured VCO₂ and Raco₂ in spontaneously breathing babies and demonstrated the feasibility of applying the isotopic technique during mechanical ventilation.

Methods

PATIENTS

Eleven spontaneously breathing VLBW (birth weight < 1500 g) babies were studied. All had clinically indicated venous access and weighed < 1500g at the time of the study. Four were breathing ambient oxygen, seven were breathing air. Feeds were either expressed breast milk (n = 8) or a standard preterm formula (n = 1) administered by hourly intragastric bolus. One infant received total parenteral nutrition, and one both total parenteral nutrition and expressed breast milk. Table 1 summarises clinical details. A single ventilated baby was later studied to address problems of sampling from the endotracheal tube and to examine within patient variation in Raco₂. St George's Healthcare NHS Trust research ethics committee approved the study; informed written consent was obtained from the parents.

Figure 1 Design of the study.

DESIGN OF EXPERIMENT

Figure 1 summarises the protocol. Intragastrically fed babies were changed from hourly bolus feeds to continuous feeding at least one hour before the start of the study. A bolus dose of tracer (NaH[13]CO₃) was given intravenously, followed by continuous tracer infusion. Simultaneously a Deltatrac II metabolic monitor (Datex, Helsinki, Finland) was used to measure VCO₂ throughout the first hour, after which breath was sampled intermittently to measure isotopic enrichment. Babies were routinely nursed in incubators, and temperature, heart rate, respiratory rate, SaO₂, continuously monitored.

ISOTOPE

NaH[13]CO₃ (99% ¹³C) was obtained from Promocem Ltd, Welwyn Garden City, Herts, UK. A 2 mg portion was diluted in 1 ml unlabelled 2.74% NaHCO₃ and packaged in 5 ml sterile pyrogen-free ampoules by the Northwick Park and St Mark's NHS Trust Pharmacy.

MEASUREMENT OF RACO₂

A priming dose of NaH[13]CO₃ (0.25 mg/kg) was given after collection of two baseline samples to measure background ¹³C enrichment. NaH[13]CO₃ (0.2 mg/kg/h) was then infused continuously using an IVAC syringe driver (Alaris, Basingstoke, Hants, UK). Isotope dosage was measured by weighing on a Sartorius top loading balance with a resolution of 1 mg. A loose fitting face mask and 10 ml syringe were used to sample breath at 30 minute intervals. Breath was then expelled into evacuated tubes (Exetainers; Labco Ltd, High Wickham, Bucks, UK) for storage at room temperature. ¹³C enrichment was measured by isotope ratio mass spectrometry at the Bureau of Stable Iso-

tope Analysis, Brentford, Essex, UK. (The Bureau provides a postal service at commercial rates.) δ (‰) values were converted into atom percent excess (APE) using the formula: APE = [0.01123726/(0.01123726 + 1000)] × 100

The rate of appearance of CO₂ (RaCO₂) was then calculated using the standard single pool model equation: RaCO₂ (µmol/kg/min) = F(E/E₂) − 1

in which F represents the rate of infusion of NaH[13]CO₃ (µmol/kg/min), E, the enrichment of infused (99% APE), E₂, the ¹³C enrichment of expired breath at steady state (in APE). RaCO₂ was then converted into ml/kg/min, standard temperature and pressure dry (STPD) by applying Avogadro’s constant (1 mole of gas = 22.4 litres, STPD). Breath isotopic enrichment was plotted against time, and the plateau defined according to the convention of taking four or more consecutive points with a coefficient of variation of < 5%.

MODEL OF HCO₃⁻ KINETICS

The single pool model assumes that all bicarbonate administered and CO₂ produced by metabolism enters and leaves the body from a central rapid turnover pool. This eventually attains equilibrium with slow turnover pools. The factor c corrects for overestimation of breath ¹³C enrichment when a study is too short for this state to be attained.

Figure 2 Model of CO₂/HCO₃⁻ kinetics. All infused tracer and HCO₃⁻/CO₂ generated by metabolism enters and leaves the body from a central rapid turnover pool. This eventually attains equilibrium with slow turnover pools. The factor c corrects for overestimation of breath ¹³C enrichment when a study is too short for this state to be attained.
Ra\(\text{CO}_2\) is then given by:
\[ V\text{CO}_2 = c\left(\text{Ra}\text{CO}_2\right) \] (4)
which can be rearranged as:
\[ c = \frac{V\text{CO}_2}{\text{Ra}\text{CO}_2} \] (5)

MEASUREMENT OF V\(\text{CO}_2\)
Respiratory elimination of \(\text{CO}_2\) (\(V\text{CO}_2\)) was measured using a commercially available open circuit indirect calorimeter (Deltatrac II metabolic monitor). This device offers a choice of four preset canopy flow rates: “baby” (3.1 litres/min), “child” (10.3 litres/min), “adult”, and “obese adult”. In accordance with manufacturer’s recommendations, the instrument was warmed up for at least 30 minutes before two point calibration with room air (\(\text{CO}_2\) content assumed to be 0.04%) and Datex calibration gas (4.99% \(\text{CO}_2\), later verified by BOC Analytical Division, Crawley, Sussex, UK). The baby’s head and shoulders were placed under the transparent perspex canopy, and a partial seal created by tucking the integral flexible skirt beneath the body and mattress. The child flow range was chosen because Bauer et al. have concluded that a flow rate of at least 4.5 litres/min is required for accurate measurement of \(V\text{CO}_2\) using the Deltatrac in canopy mode. We also formally compared child and baby range canopy flow rates by studying four VLBW continuously fed babies over four consecutive one hour periods in a randomised 4 × 4 latin square design (see Results).

ADDITIONAL IN VITRO CALIBRATION OF THE DELTATRAC
The manufacturer recommends that the canopy flow is calibrated by burning alcohol at rates approximating adult \(\text{O}_2\) consumption and \(\text{CO}_2\) production. It must then be assumed that canopy flow changes proportionately when the device is switched between baby, child, and adult ranges. We chose in addition to calibrate the instrument directly in child and baby settings by infusing medical grade \(\text{CO}_2\) (confirmed as 100% \(\text{CO}_2\) by BOC Analytical Division) at rates similar to those we encountered clinically.

A mannequin was placed under the canopy to simulate a baby, and \(\text{CO}_2\) injected at constant rate using a Harvard rotating screw syringe driver with four parallel mounted gas tight 50 ml polypropylene syringes. Connections were made with gas tight three way taps and PVC lines (Datex). Syringes were flushed four times with \(\text{CO}_2\) to remove air before use. Timed collections of water delivered in the range 4–12 ml/min showed that 2.777 ml was reproducibly displaced by each revolution of the syringe driver screw. The \(\text{CO}_2\) injection rate was therefore established by counting rotations of the screw using a vane and slotted optical switch connected to a microcomputer. Gas temperature was measured using an ELAB type CTD thermocouple (ELAB, Copenhagen, Denmark) and volumes corrected to STPD.

Results
MEASUREMENT OF \(\text{RaCO}_2\)
Analysis of variability in background \(^{13}\text{C}\) enrichment in the 11 pairs of breath samples collected at baseline of each study showed that there was a small but statistically significant variation between studies (one way analysis of variance, \(F = 7.66; 10, 11\) df; \(p < 0.001\)). This is allowed for in the calculation of APE and \(\delta\). Isotopic steady state was achieved in eight subjects by 120 minutes and in all 11 by 200 min-

The relation between CO₂ injection rates (fig 4), showing greatest discrepancy at ml/kg body weight/min. ml/min STPD (table 2), equivalent to 8.5 (1.7) intake, or VCO₂ was apparent. correlation between included unity. No statistically significant evidence intervals of the mean (0.87 to 1.03)

DERIVATION OF FRACTIONAL RECOVERY RATE, c

In vitro calibration showed that the Deltatrac consistently underestimated true CO₂ injection rate (fig 3). Mean (SD) RaCO₂ was 9.6 (2.1) ml/min STPD (table 2), equivalent to 8.5 (1.7) ml/kg body weight/min.

MEASUREMENT OF VCO₂

In vitro calibration showed that the Deltatrac consistently underestimated true CO₂ injection rates (fig 4), showing greatest discrepancy at highest rates. The relation between CO₂ injection rate (y) and simultaneous Deltatrac measurement (x) using the child canopy flow setting was given by y = 1.12x (n = 16, r = 0.99; SD residuals = 0.36). As there was no intercept term (a), the regression coefficient (slope, b = 1.12) was subsequently used to correct values of VCO₂ measured in vivo. A similar calibration constant was obtained in the baby flow range (y = 1.13x (n = 15, r = 0.99; SD residuals = 0.16)).

Within patient measurements of VCO₂ made using the baby and child flow rates were not significantly different (baby range median 7.4 ml/min; child range median 7.9 ml/min; p = 0.7, Kruskal-Wallis; four babies × four one hour studies). Mean (SD) VCO₂ measured with the Deltatrac in the 11 babies studied was 9.0 (2.0) ml/min, equivalent to 7.9 (1.3) ml/kg body weight/min. RaCO₂ exceeded VCO₂ in seven.

STUDY OF A VENTILATED BABY

To assess the feasibility of measuring RaCO₂ in small ventilated babies, we studied a 20 day old 658 g infant with chronic lung disease (gestational age 25 weeks, birth weight 587 g). We and others have found it impossible to measure VCO₂ using the Deltatrac in such circumstances. She was continuously fed with human milk through a nasogastric tube and ventilated with a Babylog 8000 plus ventilator (Dräger, Hemel Hempstead, Herts, UK) at constant pressure, rate, and inspired time settings throughout the 24 hour study period. Fio₂ varied between 0.4 and 0.7, and PCO₂ between 5.0 and 6.5 kPa. A primed continuous intravenous infusion of NaH¹³CO₃ was administered at a constant rate for 24 hours using doses given above (see Methods). Breath samples were collected using a syringe connected to a side port (designed for surfactant administration) on the endotracheal tube connector. Figure 5 shows the results. RaCO₂ (STPD) was measured over three periods: plateau 1 (260—410 minutes, n = 4, RaCO₂ = 5.5 ml/min); plateau 2 (630—695 minutes, n = 5, RaCO₂ = 4.9 ml/min); plateau 3 (1175—1348 minutes, n = 5, RaCO₂ = 5.4 ml/min).

Discussion

Arterial PCO₂ reflects a balance between the rate at which CO₂ is eliminated through the lungs and the rate at which it is produced by metabolism. Much attention in neonatal intensive care has been focused on controlling elimination by mechanical ventilation, but less has been paid to minimising CO₂ production by varying the amount and type of dietary fuel supplied. Inherent difficulties in measuring the rate of CO₂ production in small ventilated babies may be one reason why nutritional interventions have been largely overlooked. We have shown that the labelled bicarbonate infusion technique can be used to measure simply the rate of CO₂ production in small ventilated babies, whether spontaneously breathing or mechanically ventilated. We found moreover that estimates of VCO₂ and RaCO₂ in this group are comparable even in a short term study lasting two to four hours. In this respect, VLBW infants differ significantly from older children and adults.

Our estimate of fractional recovery rate, c, in this sample of babies was 0.95, with 95% confidence intervals 0.73 to 1.2 including unity.

Figure 4 Prediction of true VCO₂ from Deltatrac measurement.

Figure 5 Study of ventilated 658 g infant. Plot of breath isotopic enrichment (atom percent excess (APE)) against time. See text for estimates of RaCO₂.
This is substantially higher than values previously reported in short term studies. Consideration of the model would suggest that this reflects rapid equilibration of infused isotope between body pools, with minimal trapping in slow turnover pools such as bone. This seems physiologically plausible, as VLBW babies have a low bone and fat mass, high extracellular fluid volume, and high resting metabolic expenditure relative to older infants. The only other neonatal study we have identified estimated the mean value for $c$ as 0.77 but recruited more mature babies (mean birth weight 2120 g, mean study weight 2100 g), only three of whom weighed <1500 g. Estimates in older children and adults have varied from 0.5 to 1.06, although a value of 0.8 is commonly assumed in substrate oxidation studies. In a comparative study, RaCO$_2$ was found to be much faster in children than in adults, which might further support our hypothesis. The derivation of equation 4 requires an assumption that CO$_2$ is eliminated only through the lungs. This may be questionable, particularly in immature babies. In adults, about 1% of CO$_2$ is lost across the skin and less than 5% is excreted in the urine, although the exact amount is dependent on urine pH. Although we have found no estimates of skin loss in VLBW infants, a study of infants weighing <1000 g (gestational age 23–29 weeks) confirmed that cumulative bicarbonate loss over the first four days of life was only 1.9 (0.5) mmol/kg (mean (SD)). This is equivalent to an equimolar non-respiratory loss of 7.4 µl CO$_2$/min/kg body weight. These errors can therefore be considered insignificant.

A further potential source of error in the measurement of RaCO$_2$ is fluctuating background $^{13}$C enrichment during the course of a study. Control studies have been undertaken in which subjects underwent the experimental protocol without bicarbonate administration. Most, however, have regarded this as an extremely small potential error and assumed that the initial background enrichment does not change. Some consider indirect calorimetry the ideal method for measuring CO$_2$ production, but substantial errors can arise when studying small babies. Our in vitro experiment indicated that particular care is required to calibrate the Deltatrac for use with small infants. Other preliminary experiments (see Results) showed no significant difference between values obtained in vivo using baby and child settings. We took great care to simulate the in vivo situation when calibrating the Deltatrac, to the extent that we used physiologically appropriate rates of CO$_2$ injection, validated the purity of gas used, and placed a baby sized mannequin within the canopy and flexible skirt. If calibration had not been performed, a considerable underestimate of VCO$_2$ would have been made.

As we have shown, potential errors of different sorts apply to the measurement of both RaCO$_2$ and VCO$_2$. This is not surprising, as they measure different aspects of CO$_2$ metabolism. One (VCO$_2$) measures the elimination of CO$_2$; the other (RaCO$_2$) measures the turnover (or flux, Q) of bicarbonate within the body pool. In steady state, the latter is equivalent to both the rate of appearance (Ra) and rate of disappearance (Rd). Measurement of arterial blood CO$_2$ status at the beginning and end of each study may have helped to confirm that the bicarbonate/CO$_2$ pool was in steady state during each study, but we did not feel blood sampling ethically justifiable. Participants showed stable cardiorespiratory measurements throughout and most were breathing air. Moreover the satisfactory enrichment plateaux (fig 3) observed in the 11 studies themselves constitute evidence that the bicarbonate pool was in steady state.

The 11 studies we describe were conducted only for two to four hours, and we have not implied measurements to be representative of longer periods. In deriving $c_i$, we have made comparisons only between quantities simultaneously measured in the same baby. We performed only one 24 hour study, principally to assess the feasibility of applying the technique in a ventilated baby (fig 5). Although we attempted to measure VCO$_2$ by connecting the Deltatrac monitor to the expiratory port of the ventilator (Dräger Babylog 8000 plus), we obtained no satisfactory measurements, probably because a blow off mechanism in the ventilator allows inspiratory and expiratory gases to mix under certain circumstances. The many problems associated with the measurement of VCO$_2$ during mechanical ventilation have been well described previously. In contrast, measurement of RaCO$_2$ was easily accomplished using the labelled bicarbonate technique and yielded comparable values at the three plateau periods studied.

In summary, we have shown that the labelled bicarbonate infusion technique is easily applicable to the experimental protocol without bicarbonate administration. In contrast with experience with older children and adults, the adjustment required for retention of infused isotope in short term studies is negligible in this group of patients. This confirms the value of determining the fractional recovery rate, $c$, for individual patient groups. The simplicity of this technique offers new opportunities to study the interaction between fuel metabolism and respiratory function even in the smallest ventilated babies.

We acknowledge the collaboration of Professor David Halliday who undertook breath analyses at the Bureau of Stable Isotope Analysis, Brentford. The study was funded by the St George’s Hospital Special Trustees Research Fund.
