Motor skills in adolescents with low birth weight

K A I Evensen, T Vik, J Helbostad, M S Indredavik, S Kulseng, A-M Brubakk

Background: Minor motor problems have been reported in low birthweight children, but few studies have assessed motor skills in adolescents.

Objective: To examine the prevalence of motor problems in adolescents with low birth weight.

Method: Fifty four very low birthweight (VLBW: birth weight ≤ 1500 g), 59 term small for gestational age (SGA: birth weight < 10th centile), and 83 control (birth weight ≥ 10th centile at term) children were assessed with the Movement assessment battery for children (Movement ABC) at the age of 14 in a population based study.

Results: One in four VLBW children (odds ratio (OR) 9.3, 95% confidence interval (CI) 2.5 to 34.5) and one in six SGA children (OR 4.7, 95%CI 1.2 to 18.4) (P=0.04) had motor problems compared with controls (3.7%). There were no sex differences in motor problems in the VLBW group, and the increased risk was consistent across the continuum of the Movement ABC. For SGA children, the increased risk of motor problems was particularly in manual dexterity in boys.

Conclusion: VLBW and SGA adolescents have increased risk of motor problems compared with control children.

Low birth weight is the most important risk factor for perinatal death and morbidity, and may result from short gestation and/or intrauterine growth retardation.

Advances in prenatal care, obstetrics and neonatal medicine over the last 20 years have improved short term prognosis, but at the same time there is increasing concern about long term outcome for these children.

Children with a birth weight ≤ 1500 g (very low birth weight: VLBW) are especially at risk of later developmental problems. These children have an increased risk of cerebral palsy and other major handicaps, such as blindness, deafness, and subnormal intelligence. Motor problems seem to be the most common minor impairment in VLBW children. Several studies have reported an increased prevalence of motor problems in VLBW children at preschool and school ages. There have been few reports on motor skills in VLBW adolescents. However, a high prevalence of motor problems in 12–13 year old VLBW children has been reported.

Children who have been growth retarded in utero are usually diagnosed by having a low birth weight adjusted for gestational age (small for gestational age: SGA). SGA infants born at term are at some risk of later developmental problems, as indicated by a slightly increased risk of cerebral palsy and minimal neurological dysfunction. Studies on motor problems among younger SGA children born at term have shown inconsistent results and we are not aware of such studies in adolescents.

In this study, we wanted to examine whether VLBW and term SGA children have an increased prevalence of motor problems in adolescence compared with control children.

MATERIAL AND METHODS

Study design and study population

This is a follow up study of two groups of low birthweight children: (a) preterm VLBW (birth weight ≤ 1500 g); (b) term SGA (birth weight < 10th centile). Details of the study are presented in the preceding article.

A total of 54 VLBW (29 boys, 25 girls), 59 SGA (27 boys, 32 girls), and 83 control (35 boys, 48 girls) children had a motor assessment. Table 1 shows gestational age and anthropometric measurements. Fifteen VLBW, 33 SGA, and 27 control children did not consent to participation. There were no significant differences in maternal age, duration of pregnancy, the infants’ birth weight, body length, and head circumference between those who participated and those who did not consent to participate in any of the groups.

Methods

Each child was tested with the Movement assessment battery for children (Movement ABC) by the first author (physiotherapist), who was blinded to the adolescent’s group assignment. The Movement ABC consists of eight items, scored between 0 (optimal score) and 5 and grouped as three subscores: manual dexterity, ball skills, and static/dynamic balance. Scores < 5th centile indicate definite motor problems. We used the highest age band, designed for 11–12 year old children. As the study population was examined at age 14, we used the 5th centile derived from the control group, corresponding to a total score of 14, well in accordance with the 5th centile in the manual.

In this study, intrater reliability with respect to timing and counting was assessed by videotaping 34 children. The intraclass correlation (ICC 1.1) was found to be 0.9996 for timing (item 1) and 0.9935 for counting (item 4). Five children (four VLBW children, one control) were not able to complete all test items. Analysis on item scores and subscores were performed by both using all available data and excluding subjects with incomplete data.

Cerebral palsy was diagnosed and classified as diplegia, hemiplegia, or quadriplegia by project paediatricians. An estimate of intelligence quotient (IQ_{est}) was calculated using four subscales of Wechsler intelligence scales (WISC-III). We defined “low IQ_{est}” as below 2 SDs of the control group mean value. Socioeconomic status was calculated according to Hollingshead’s two factor index of social position.

VLBW, Very low birth weight; SGA, small for gestational age.

What is already known on this topic
- VLBW children have increased risk of motor problems
- Studies on term SGA children have shown inconsistent results

What this study adds
- Prevalence of motor problems in VLBW and term SGA adolescents, based on Movement ABC
- Description of motor problems in these groups, highlighting:
  - Low birthweight adolescents have increased risk of motor problems
  - VLBW adolescents have widespread motor problems
  - SGA boys have specific problems in manual dexterity

Ethics
The regional committee for medical research ethics approved the study protocol. Written informed consent was obtained from both adolescent and parents.

Statistical analysis
SPSS 11.5.1 was used for data analysis, and a significance level of 0.05 was chosen. Three-group comparisons were made using one way analysis of variance for variables with a normal distribution, and Kruskal-Wallis for variables with a non-normal distribution. If a significant difference was found between the three groups, two-group comparisons were made using Scheffe’s post hoc test for variables with a normal distribution and Mann-Whitney U test for variables with a non-normal distribution. The χ² test was used to analyse differences in proportions between groups.

Odds ratio (OR) was calculated and used as an estimate of the relative risk of motor problems for children with low birth weight compared with the control group. We applied bivariate logistic regression analysis for variables associated with group and/or outcome measures to calculate adjusted odds ratios, in order to control for possible confounding factors.

RESULTS
At follow up, VLBW and SGA children were shorter, lighter, and had smaller head circumference than controls, whereas body mass index did not differ between the three groups (table 2). Socioeconomic status was lower in the VLBW group than in the control group. There were no differences between groups with regard to age, sex, or handedness.

Six (11%) VLBW children (four diplegia, one hemiplegia, one quadriplegia) and one (2%) SGA child (diplegia) had cerebral palsy. Four children with cerebral palsy completed all test items. Ten (18.5%) VLBW, four (6.8%) SGA, and three (3.6%) control children had a low IQest.

The VLBW group had higher mean values than the control group in total ABC score and all subscores (table 3). This persisted after the exclusion of children with cerebral palsy, low IQest; and/or children with incomplete test results from the analysis (data not shown). There were no differences in mean subscores or total ABC score between the SGA group and the control group.

Boys had poorer manual dexterity than girls in both the SGA and control groups (table 4). This sex difference was not found in the VLBW group. There were no differences in ball skills, balance, and total ABC scores between boys and girls in the VLBW or the control group. In the SGA group, boys scored better than girls in ball skills, but worse in balance and total ABC score.

Thirteen of 50 (26%) VLBW children (OR 9.3, 95%CI 2.5 to 34.5 v controls), and nine of 59 (15.3%) SGA children (OR 4.7, 95%CI 1.2 to 18.4 v controls) had motor problems compared with three of 82 (3.7%) control children (table 5). After exclusion of the children with cerebral palsy, the risk of a total ABC score < 5th centile was slightly reduced for both VLBW (OR 7.1, 95%CI 1.8 to 27.4) and SGA children (OR 4.2, 95%CI 1.1 to 16.6). After exclusion of children with low IQest, the results showed a small reduction in risk of motor problems in the VLBW (OR 6.1, 95%CI 1.5 to 24.6) and the SGA group (OR 3.7, 95%CI 0.9 to 15.0).

Compared with the control children, the VLBW children showed poorer skills in both manual dexterity and balance, and the SGA children showed an increased risk of poor manual dexterity. The OR for the subscores remained essentially the same after exclusion of children with cerebral palsy, low IQest, and the children who did not complete the whole test (data not shown).

Weight and socioeconomic status at 14 years of age were the only factors associated with both birthweight group and outcome variables; higher weight and lower socioeconomic status were associated with poorer balance and total ABC score. When socioeconomic status was included in the logistic regression analysis, the risk of motor problems was unchanged in the VLBW group and slightly reduced in the SGA group (OR 4.0, 95%CI 1.0 to 15.9). When weight was included in the logistic regression analysis, the risk of poor balance increased in both low birthweight groups (table 5). Even though weight was not associated with the other...
IQest suggest that poor motor skills are prevalent among low birthweight children and a control group. When children with cerebral palsy and/or low IQest were excluded, the results changed slightly (table 5).

Factors associated with birthweight group (height and head circumference) or with one or more of the outcome measures (sex, handedness, and body mass index) were also separately included in logistic regression analysis as potential confounders. The only factor contributing to a major change in OR was height, and, after adjustment for height, the risk of poor manual dexterity increased in the SGA group (OR 12.7, 95%CI 2.7 to 60.1).

The increased risk of motor problems in the VLBW group was essentially the same for boys and girls. In the SGA group, the increased risk was found only among boys (table 6). This was most pronounced for poor manual dexterity, where SGA boys showed five times the risk of control boys (OR 5.2, 95%CI 2.7 to 60.1).

The reason why 75 adolescents (28%) did not want to participate in this study is not known. We found, however, no significant differences between mothers and children who participated and those who did not. It is therefore unlikely that the results are due to selection bias.

Poor growth has been described in VLBW and SGA adolescents, and was also found for the VLBW and the SGA adolescents in our study compared with the controls. Weight and partly height were identified as possible confounding factors of the association between low birth weight and motor problems. Higher weight and height seemed to increase the risk of motor problems. When we adjusted for these factors, the relative risk of motor problems in the two low birthweight groups was even higher. Thus the increased risk of motor problems in VLBW and SGA children cannot be explained by poor postnatal growth.

Our finding of a high prevalence of motor problems in VLBW children is consistent with the literature. Most studies have examined younger children and have found that 6–8 year old VLBW children have worse scores on the Movement ABC than controls. Few studies have examined motor problems in adolescents. Powls et al found that 34% of 12–13 year old children with a birth weight < 1251 g scored ≤ 5th centile on the Movement ABC. This may be well comparable to the finding in our study, considering that our VLBW group is defined by a birth weight ≤ 1500 g.

We are not aware of any studies that have assessed motor function in SGA adolescents. Results for younger SGA children are inconsistent. One study did not find any motor problems in SGA children aged 3–5 years, another reported borderline significance of increased incidence of motor problems, and one found poorer motor skills for 7 year old SGA children than for controls. In our study a substantial proportion of the SGA children had motor problems at 14 years of age. These discrepancies may be due to different age groups and methods. However, Sommerfelt et al found that

### DISCUSSION

In this study, we found that one in four VLBW children and one in six SGA children had motor problems at 14 years of age. For VLBW children the increased risk was consistent among boys and girls, whereas for SGA children the risk was particularly high for boys with respect to manual dexterity. Analyses excluding children with cerebral palsy and/or low IQest suggest that poor motor skills are prevalent among low birthweight children without known physical and/or mental deficiencies.

Values are mean (SD). *p < 0.05, **p < 0.01, ***p < 0.001 v controls. VLBW, Very low birth weight; SGA, small for gestational age.

The 10th centile definition of SGA is crude, and a certain proportion of normal small infants could have been classified as SGA, whereas some infants who may have been growth retarded in utero could have been classified as controls. Nonetheless, we found that the SGA group had a fivefold increased risk of motor problems compared with the control group. If SGA children were classified as controls, or vice versa, this would probably have resulted in smaller differences between the groups. The VLBW children were classified according to a birth weight ≤ 1500 g. We are aware that some of the children in the VLBW group may have been growth retarded. However, they were all born preterm, and we have chosen to treat them as a group in this study as a contrast with the low birthweight children born at term.

The increased risk of motor problems in the VLBW group was even higher. Thus the increased risk of motor problems in VLBW and SGA children cannot be explained by poor postnatal growth.

Our finding of a high prevalence of motor problems in VLBW children is consistent with the literature. Most studies have examined younger children and have found that 6–8 year old VLBW children have worse scores on the Movement ABC than controls. Few studies have examined motor problems in adolescents. Powls et al found that 34% of 12–13 year old children with a birth weight < 1251 g scored ≤ 5th centile on the Movement ABC. This may be well comparable to the finding in our study, considering that our VLBW group is defined by a birth weight ≤ 1500 g.

We are not aware of any studies that have assessed motor function in SGA adolescents. Results for younger SGA children are inconsistent. One study did not find any motor problems in SGA children aged 3–5 years, another reported borderline significance of increased incidence of motor problems, and one found poorer motor skills for 7 year old SGA children than for controls. In our study a substantial proportion of the SGA children had motor problems at 14 years of age. These discrepancies may be due to different age groups and methods. However, Sommerfelt et al found that
5 year old SGA children had lower scores than controls using the Grooved Pegboard test, which may be consistent with the increased risk of poor manual dexterity in the SGA group in our study. The main difference in our results between VLBW and SGA children is that VLBW children have poor motor function across the continuum of the Movement ABC, while SGA children have poor manual dexterity, and poor balance after adjustment for weight. In the VLBW group, motor problems were seen for both boys and girls, while motor problems in the SGA group were found especially for boys. These findings may indicate more global impairment in VLBW children, suggesting different pathophysiological mechanisms for the motor problems in VLBW and SGA children.

A vulnerable area of the developing brain is the periventricular white matter containing the large motor tracts. Lesions in this area may be closely related to VLBW. The high prevalence of motor problems in the VLBW group may therefore be consistent with the previously reported high prevalence of brain lesions seen on magnetic resonance imaging in VLBW children.

In the parasagittal region of the full term brain, vascular border zones are vulnerable to a fall in perfusion pressure which can cause subcortical necrosis. In SGA adolescents, a possible pathophysiological explanation for the poor manual dexterity may be perinatal circulation disturbances and hypoxia in these watershed areas, as lesions in the parasagittal region involve upper, more than lower, limbs.

Balance was also affected in SGA adolescents after adjustment for weight. The cerebellum develops during the last months of pregnancy, and is involved with the coordination of motor activity and mechanisms that influence and maintain posture and equilibrium. Animal studies have shown that growth restriction before and after birth may result in reduced myelination and weight of the cerebellum. Growth restriction of the cerebellum may be responsible for both the poor balance and fine tuning of movements contributing to poor manual dexterity in SGA children.

Male fetuses have higher growth velocities than female fetuses in the third trimester, when the human brain more than doubles its weight. It is therefore possible that SGA boys may be more vulnerable to growth restriction during this period than girls.

Previous studies have shown that motor problems are associated with poor academic performance, as well as emotional and social problems. Poor motor skills may be more problematic for these children in early adolescence, as the school curriculum introduces a wide range of new activities which may highlight their motor problems. Poor manual dexterity would in particular be likely to affect writing skills, and may be increasingly important in further education.

In conclusion, VLBW and SGA adolescents have increased risk of motor problems compared with control children. Whether this is due to prenatal, perinatal, or postnatal factors cannot be answered in this study.
