Neonatal volume guarantee ventilation: effects of spontaneous breathing, triggered and untriggered inflations

N McCallion,1,4 R Lau,1 C J Morley,1,2,3 P A Dargaville2,3

ABSTRACT

Background: During volume guarantee (VG) ventilation the peak inflating pressure (PIP) for each ventilator inflation is adjusted to ensure the expired tidal volume (VTe) is close to the set VTe. Differences in the PIP between inflations triggered by the infant’s inspirations and untriggered inflations are seen.

Aim: To investigate the effects of triggered and untriggered inflations on PIP and VTe.

Methods: Neonates were ventilated with the Dräger Babylog 8000 using assist control (synchronous intermittent positive pressure ventilation) and VG modes. Continuous recordings of ventilator pressures and tidal volumes were made at 200 Hz for 10 minutes.

Results: In 10 infants, 6540 inflations were analysed, of which 4052 (62%) were triggered. Triggered inflations had a significantly lower mean (SD) PIP than untriggered inflations: 12.9 (4.9) vs 17.0 (3.3) cm H2O, (p<0.001). Despite this, there was no significant difference in the VTe of each type of inflation (103% and 101% of the set VTe, respectively). When a triggered inflation was immediately preceded or followed by an untriggered inflation the PIP changed by about 5 cm H2O. Between adjacent inflations of the same type, the change in PIP was less than 3 cm H2O: for triggered inflations it was 0.11 (1.50) cm H2O and for untriggered inflations 0.06 (1.53) cm H2O.

Conclusion: During VG ventilation with the Dräger Babylog 8000 the PIP was 4 cm H2O lower during triggered inflations than untriggered inflations, although the expired tidal volumes were similar.

This study aimed at investigating the effects of the infant’s spontaneous breathing efforts and triggered or untriggered inflations on PIP and VTe.

Designing a ventilator for infants: Effect of triggered and untriggered inflations on lung mechanics

Abstract

The aim of this study was to evaluate the effect of triggered and untriggered inflations on lung mechanics in preterm infants. Infants were ventilated using a custom-designed ventilator, and triggered inflations were identified by a positive end expiratory pressure (PEEP) of 5 cm H₂O. A set inspiratory tidal volume (VTₑ) of 5 ml/kg was used, and inspiratory time was set at 0.3 seconds. The peak inspiratory pressure (PIP) was 30 cm H₂O, and fractional inspired oxygen (O₂) was 0.28 (0.21–0.30). All had acceptable blood gases and maintained adequate ventilation and oxygenation throughout: mean (SD) SpO₂ 96 (7) %, TcCO₂ 6.2 (1.5) kPa (48 (10) mm Hg) and heart rate 142 (14) beats/min.

RESULTS

Ten infants ventilated through an endotracheal tube were studied for 30 minutes each, and 10 minutes of movement-free recording selected from each study. About 600 consecutive inflations were analysed in detail for each infant. In total 6540 inflations were analysed. Of these, 4052 (62%) were triggered and 2488 (38%) not triggered. Figure 2 illustrates the appearance of triggered and untriggered inflations.

The infants' characteristics, median (range), were: gestational age 28 (24–37) weeks, weight 1275 g (630–3110 g), day of life when studied 3 (1–24), set VTₑ at the time of the study 3.85 (2.8–4.7) ml/kg and fractional inspired oxygen 0.28 (0.21–0.30). All had acceptable blood gases and maintained adequate ventilation and oxygenation throughout: mean (SD) SpO₂ 96 (7) %, TcCO₂ 6.2 (1.5) kPa (48 (10) mm Hg) and heart rate 142 (14) beats/min.

Effect of triggered and untriggered inflations on peak inflation pressure

Overall triggered inflations (n = 4053) had a lower PIP at 12.9 (4.9) cm H₂O than untriggered inflations (n = 2488) at 17 (8.5) cm H₂O (p < 0.001). The mean (95% CI) PIP for triggered inflations was significantly lower than for untriggered inflations by 4.1 (3.9 to 4.3) cm H₂O. When triggered inflations were immediately followed by an untriggered inflation (n = 838) the peak inflation pressure increased by a mean (SD) of 5.1 (6.7) cm H₂O. When untriggered inflations (n = 839) were followed by a triggered inflation the PIP fell by 4.8 (6.7) cm H₂O.

Between adjacent triggered inflations (n = 3209) the change in PIP was 0.11 (1.50) cm H₂O and between adjacent untriggered inflations (n = 1644) it was 0.06 (1.53) cm H₂O. Therefore pressure changes between inflations of the same type were less than 3.0 cm H₂O for 97.7% of the time.

Effect of triggered and untriggered inflations on expired tidal volume

Despite the differences in PIP between the two types of inflations there was no significant difference between the delivered VTₑ as a percentage of the set VTₑ: triggered 103% and untriggered 101%.

When triggered inflations were immediately followed by an untriggered inflation (n = 838) and the PIP increased the VTₑ fell by 0.26 (2.06) ml/kg. When untriggered inflations were followed by a triggered inflation (n = 839) the VTₑ fell by 0.26 (2.19) ml/kg.

The change in VTₑ between adjacent triggered inflations (n = 3209) was 0.04 (1.22) ml/kg and between adjacent untriggered inflations (n = 1644) it was 0.09 (1.41) ml/kg.

The set maximum PIP of 50 cm H₂O might have limited some of the inflating pressures. However, only 0.2% of the inflating pressures reached the set PIP.

Figure 1 Illustration of the way in which triggered inflation was recognised for this study. The vertical dashed line shows the onset of the inflation pressure. Arrow A indicates the inspiratory flow starting just before the onset of inflation. Arrow B points to a small dip in the pressure wave just before the onset of inflation and coinciding with the onset of inspiratory flow.
DISCUSSION

We report a detailed analysis of changes in PIP and expired tidal volume for individual triggered and untriggered inflations during VG ventilation with the Dräger Babylog 8000 ventilator. This has not been possible in other studies of volume ventilation where the data have not been acquired in detail for individual inflations but have been averaged over varying periods.6 11 14

Volume-targeted modes of neonatal ventilation are used to reduce volutrauma and associated ventilator-induced lung injury that has been linked to the development of bronchopulmonary dysplasia.2 A meta-analysis comparing volume-targeted ventilation with traditional time-cycled, pressure-limited modes has shown reductions in the duration of ventilation, rates of pneumothorax and severe intraventricular haemorrhage, and shows a trend towards a reduction in the incidence of bronchopulmonary dysplasia (relative risk = 0.34 (95% CI 0.11 to 1.05)).15

When triggered and untriggered inflations were analysed separately (ie, the pressure for a triggered inflation compared with an adjacent triggered inflation, and similarly for untriggered inflations), the differences were within the manufacturer’s 3 cm H2O limit for both types for 97% of the time. However, pressure fluctuations above 3 cm H2O occurred between consecutive inflations when the inflations changed between triggered and untriggered modes. Triggered inflations, where the infant contributed to the tidal volume, were delivered with a PIP about 4 cm H2O lower than untriggered inflations.

The difference in PIP between triggered and untriggered inflations is due to the presence or absence of infant inspiratory effort. During an untriggered inflation the infant is not inspiring and so the ventilator pressure has to be sufficient to provide the set tidal volume. During a triggered inflation the infant is inspiring and contributing to the tidal volume. The VG program adjusts the peak pressure to ensure a set expired tidal volume and so the pressure needed to ensure the tidal volume with a triggered inflation is lower than with an untriggered inflation. This change in peak pressure inflation does not occur with time-cycled, pressure-limited ventilation in assist-control mode.

Our own observations have shown that pressure-limited ventilator modes which do not control the tidal volume deliver a fixed PIP independent of the infant’s respiratory effort. This results in very large changes in tidal volume as the infant varies their spontaneous tidal volume or the lung compliance changes. In this study only 62% of the inflations were triggered because the set ventilator rate of 60/min was close to the infant’s spontaneous respiratory rate; this reduced the infant’s ability to trigger the ventilator because a mandatory, or back-up inflation, was delivered before the infant had time to inspire. Our recent experience has been that with a ventilator rate lower than 60/min the proportion of triggered inflations increases. This is likely to improve the overall effect of VG ventilation when the baby is breathing spontaneously and triggering inflations.

The information in this study is specific to the Dräger Babylog 8000 plus ventilator. Other neonatal ventilators, with other methods of controlling tidal volume do not have the same...
control algorithms for triggered and untriggered modes, nor do they all target the expiratory tidal volume.

CONCLUSION
During VG ventilation with the Dräger Babylog 8000 the PIP was 4 cm H2O lower during triggered inflations than untriggered inflations, although the expired tidal volumes were similar. The fluctuations in inflating pressures during VG ventilation are an integral part of providing consistent expiratory tidal volumes for ventilated infants with variable inspiratory effort.
