ABSTRACT

Objective To compare mortality, short-term morbidity and long-term neurodevelopmental outcomes of <29 week premature infants with antenatal steroid exposure (none, incomplete and complete).

Patients and methods Multicentre retrospective cohort study, within a geographically defined area in Australia served by a network of 10 neonatal intensive care units (NICUs), of infants <29 weeks gestational age, admitted to NICUs between 1998 and 2004. Outcome measures included hospital survival, perinatal complications and functional disability at 2–3 years follow-up.

Results 2549 neonates were included; 319 (12.5%) received no exposure to steroids. Hospital mortality (OR 0.59, 95% CI 0.45 to 0.76, $p < 0.001$), intraventricular haemorrhage (IVH) (OR 0.58, 95% CI 0.42 to 0.81, $p = 0.001$) and necrotising enterocolitis (NEC) (OR 0.62, 95% CI 0.42 to 0.91, $p = 0.018$) was less likely in infants with any steroid exposure. Any steroid exposure was associated with less need for surfactant (OR 0.41, 95% CI 0.30 to 0.57, $p < 0.001$) and mechanical ventilation (OR 0.30, 95% CI 0.17 to 0.52, $p < 0.001$). Subgroup analyses demonstrated differences in outcomes only with complete steroid coverage and not with incomplete coverage. Survival benefit and reduction in the incidence of severe IVH was evident from 24 to 28 weeks. Long-term neurodevelopmental data available for 1473 survivors showed no significant difference in outcomes with steroid exposure after multivariate analysis.

Conclusions Exposure to a complete course of antenatal steroids is associated with higher infant survival rates, lower rates of severe IVH and NEC compared to an incomplete course or no exposure. Any exposure to steroids reduces the risk of moderate cerebral palsy, however, long-term neurodevelopmental outcome may not be affected by steroid exposure.

INTRODUCTION

It has long been established that administration of antenatal corticosteroids is associated with reductions in adverse health outcomes in premature infants due to the acceleration of fetal lung maturation caused by corticosteroids.¹

The first randomised control trial of antenatal betamethasone by Liggins and Howie showed reduced mortality rates and respiratory distress syndrome (RDS) in premature infants.¹ Subsequent randomised control trials have demonstrated that antenatal corticosteroid exposure leads to decreased mortality in premature infants born between 28 and 36 weeks' gestation.^{2–3} A Cochrane review of trials has also categorically demonstrated that antenatal steroids reduce the occurrence of major

What is already known on this topic

- ▶ Antenatal steroids are known to improve neonatal survival and to reduce short-term morbidities in extremely premature infants.
- ▶ There is limited data from large cohort studies comparing survival, short-term and long-term outcomes with and without steroid exposure.

What this study adds

- ▶ Antenatal steroids given to infants born <29 weeks still confer a survival benefit and reduces the likelihood of necrotising enterocolitis and severe intraventricular haemorrhage.
- ▶ Antenatal steroids may not have an impact on long-term neurodevelopmental outcomes, but further studies are required.

neonatal morbidities, such as RDS, intraventricular haemorrhage (IVH), necrotising enterocolitis (NEC); antenatal steroids also reduce the need for respiratory support and intensive care admissions.³

Neonatal intensive care entails considerable burden on the infant and family; the significant rates of disability in surviving premature infants suggest that this burden continues long after hospital discharge.⁴ When counselling parents of infants at borderline viability, in the context of instigating intensive care, the likelihood of survival, perinatal complications and adverse long-term outcomes are important concerns. Over the past few decades, the use of antenatal corticosteroids has increased and now comprises routine care to those mothers likely to deliver prematurely. For these reasons, it is pertinent to qualify these outcomes in relation to antenatal steroid exposure, to supplement what is presently known of the likelihood of adverse outcomes in premature infants.

Currently, there are large-scale studies of extremely preterm infants that examine survival and neurodevelopmental outcomes in relation to gestational age and birth weight.^{5,6} However, there is a paucity of information qualifying outcomes in relation to antenatal corticosteroid exposure. Two recent cohort studies compare mortality and perinatal morbidity outcomes according to antenatal steroid exposure, with stratification for gestational age. These studies showed reductions in mortality,^{7,8} rates of RDS and severe

IVH.⁸ However, they did not describe long-term neurodevelopmental outcomes, or the duration of exposure. Existing population studies demonstrate that neurosensory outcomes in extremely premature infants have generally improved over time.⁵ Studies conducted after the advent of antenatal corticosteroids examined neurosensory outcomes, cognitive ability, scholastic achievement and physical development following antenatal steroid administration, with follow-up of children at 5 through to 12 years of age. These demonstrated no significant differences in outcomes when compared with no steroid exposure.^{9–11} However, Doyle *et al.*,¹² has described better cognitive function in steroid-treated infants compared with non-steroid-treated premature infants. At present, there are no gestational age-stratified multicentre cohort studies that compare mortality, short-term morbidity and long-term outcomes in extremely preterm infants with and without antenatal steroid exposure.

The aims of this study were to compare mortality rates, short-term morbidity and long-term neurodevelopmental outcomes in infants with their antenatal steroid exposure (none, incomplete, complete), when born less than 29 weeks' gestation, in a large geographically defined Australian population. We hypothesised that any antenatal steroid exposure would improve infant mortality, reduce short-term morbidity and improve long-term neurodevelopmental outcomes.

METHODS

Study population and data source

This is a retrospective population-based study of premature infants treated in 10 NICUs in New South Wales (NSW) and the Australian Capital Territory (ACT). The Neonatal Intensive Care Units Data Collection is an ongoing prospective audit of infants admitted to the 10 NICUs in ACT and NSW; definitions and accuracy of this data have been examined elsewhere.¹³ The Neonatal Intensive Care Units Follow-up Data Collection (NICUS) is an ongoing statewide audit of admitted infants, at 2–3 years of age, corrected for prematurity. Approval was obtained from the NICUS study coordinator, and was approved by the ACT Health Human Research Ethics Committee (ETHLR.11.229).

All infants admitted to these NICUs between 1 January 1998 and 31 December 2004, born at less than 29 weeks gestational age were included. Infants with major congenital malformations, or known syndromes that would impact on neurodevelopment, were excluded. Neonates who were not, or could not be, resuscitated in the delivery room were also excluded from the study.

Definitions

Antenatal steroid exposure

Antenatal steroid regimens consist of betamethasone, two doses of 12 mg given intramuscularly 24 h apart, or dexamethasone, four doses of 6 mg given intramuscularly 12 h apart. A complete course of antenatal steroids was considered if all doses of steroids were received 48 h prior to delivery but less than 7 days before birth. An incomplete course of steroids was defined as those infants receiving less than 24 h steroid coverage prior to delivery. Infants given a course of steroids more than 7 days before birth were also considered as having a complete course of steroids.

Survival and short-term morbidity outcome measures

Mortality was defined as death before hospital discharge from NICU. Short-term outcomes included chronic lung disease (CLD), defined as requiring oxygen supplementation at 36 weeks postmenstrual age; NEC was staged according to Bell's classification,¹⁴ with diagnostic criteria previously described¹⁵; IVH was graded 1–4 by Papile's system¹⁶; retinopathy of prematurity was

staged I–IV according to international criteria¹⁷; presence of proven systemic infection was also examined. Also included were interventions, such as surfactant therapy, mechanical ventilation duration and length of stay in the NICU.

Long-term outcome measures

Long-term outcomes were reviewed at 2–3 years of age. Surviving children were offered a formal developmental assessment at 2–3 years age; with protocols detailed previously.¹⁸ Included were assessment of hearing, vision, neurological examination and developmental assessment using Griffiths Mental Development Scales (GMDS), scored by General Quotient (GQ) or the Mental Scale of the Bayley Scales of Infant Development-II (BSIDII), scored by Mental Development Index (MDI). Child height, weight and head circumference were also measured at follow-up. Long-term neurodevelopment outcomes were qualified as four groups of functional disability (FD) based on the presence of developmental delay (quantified by BSID-II or GMDS developmental scales), cerebral palsy (CP), hearing loss and blindness as previously described.¹⁸ Moderate/severe FD was defined as one or more of the following: developmental delay (<2SD below the mean for adjusted age determined by the GMDS or BSID-II), CP (unable to walk without aids), bilateral blindness (visual acuity <6/60 in better eye), or bilateral deafness (requiring bilateral hearing aids or cochlear implants).

Statistical analysis

Statistical analyses were performed using the Predictive Analytics Software (PASW) (PASW for Windows; Release V.18.0.2. SPSS: An IBM Company; Chicago, Illinois, USA, 2010). Data are presented as number and percentage with OR and 95% CI or median and IQR. Maternal and perinatal characteristics were compared using χ^2 test with continuity correction and t test where appropriate. Adjusted differences in survival and neurodevelopmental outcomes between those receiving and not receiving a complete course of steroids were estimated using multiple logistic regression models. These models were adjusted for significant and clinically important baseline population characteristics including maternal age, pregnancy-induced hypertension, gestational age, birth weight, gender, outborn status and assisted conception. Cut-off for entry to and removal from models was set at $p < 0.05$ and $p > 0.10$. The level of significance for all sets of analysis was set at $p < 0.05$ using 2-tailed comparisons. Significance levels were not adjusted for multiple comparisons performed.¹⁹

RESULTS

A total of 2701 infants were admitted to the NICUs during the study period; 152 were excluded with major congenital abnormalities leaving 2549 infants; 319 (12.5%) infants had no steroid exposure, 2230 (87.5%) infants recorded any or complete steroid exposure. Follow-up data at 2–3 years was obtained for 1473 infants (74.8% of those eligible for follow-up). Of these infants, 1323 (89.8%) children had received antenatal steroids (figure 1).

Profile of infants lost to follow-up

Infants numbering 497 were lost to follow-up. Those lost to follow-up were more likely to be of aboriginal ethnicity (7.3% vs 1.4%, $p < 0.001$) and outborn (16.5% vs 7.4%, $p < 0.001$). Infants lost to follow-up had a higher median birth weight (1029 vs 945 g, $p < 0.001$) and were less likely to require surfactant therapy (60.2% vs 71.4%, $p < 0.001$) or mechanical ventilation (77.3% vs 87.3%, $p < 0.001$). In those lost to follow-up, proven systemic infection was less likely (28.8% vs 40.4%, $p < 0.001$) as was CLD (26.8% vs 40.5%, $p < 0.001$), and the

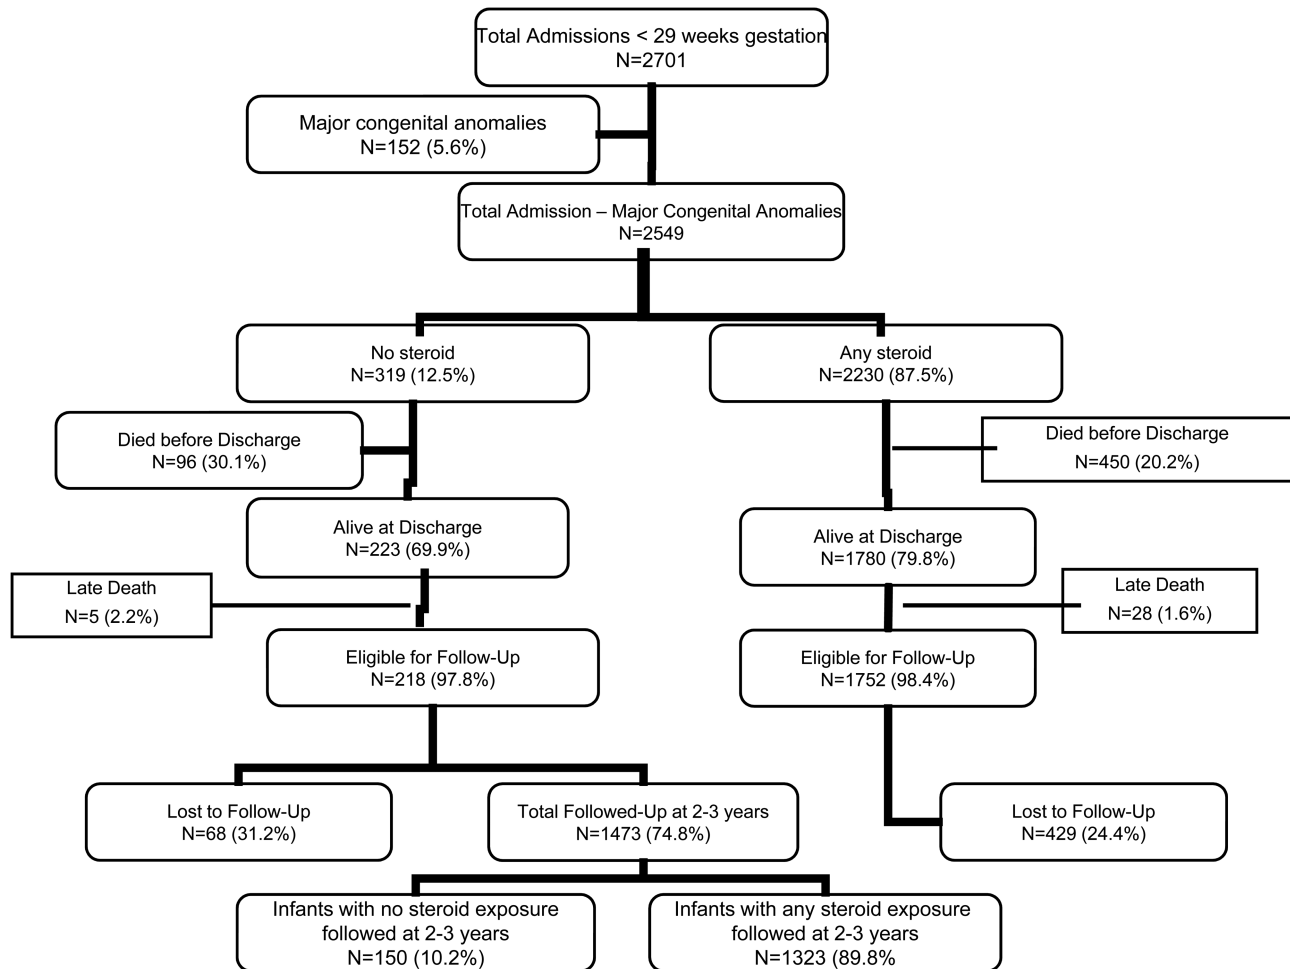

Figure 1 Profile of infants from birth to follow-up among infants admitted to NICUs between 1998 and 2004, with and without steroid exposure.

use of postnatal steroids for treatment of CLD (15.7% vs 27.7%, $p < 0.001$) when compared with those followed-up. Infants not followed-up had significantly shorter stays in intensive care (74 vs 82 days, $p < 0.001$) (data not shown).

Perinatal and neonatal characteristics of infants according to steroid exposure

Infants with no steroid exposure had lower median gestational age (26.0 vs 27.0 wks, $p = 0.012$), were more likely to be outborn

(43.9% vs 5.4%, $p < 0.001$) and were more likely to be of aboriginal ethnicity (8.8% vs 5.1%, $p = 0.010$). Mothers of infants with any steroid exposure had higher rates of pregnancy-induced hypertension (OR 2.71, 95% CI 1.72 to 4.29, $p < 0.001$) and were more likely to be older (median age 30 vs 28 years, $p < 0.001$) (table 1). There was no significant difference in antenatal steroid exposure for primiparous pregnancies ($p = 0.22$), multiple pregnancies ($p = 0.18$), exposure to chorioamnionitis ($p = 0.1$), patent ductus arteriosus ($p = 0.29$), retinopathy of prematurity grade 3 or 4 ($p = 0.98$), duration of ventilation ($p = 0.85$), CLD (0.16) and postnatal steroid use ($p = 0.5$).

Mortality and major neonatal morbidities

For infants receiving any steroid coverage, mortality rates were significantly lower (30.1% vs 20.2%, OR 0.59, 95% CI 0.45 to 0.76; $p < 0.001$) and IVH was significantly less likely (OR 0.58, 95% CI 0.42 to 0.81, $p = 0.001$), as was NEC (OR 0.62, 95% CI 0.42 to 0.91, $p = 0.018$). Furthermore, steroid exposure was associated with a reduced need for surfactant therapy (OR 0.41, 95% CI 0.30 to 0.57, $p < 0.001$) and mechanical ventilation (OR 0.30, 95% CI 0.17 to 0.52; $p < 0.001$) (table 1).

Duration of steroid exposure

Subgroup analysis comparing incomplete (<24 h) steroid exposure to no steroid exposure revealed differences in mortality and rates of perinatal morbidities were not statistically significant (table 2). Significantly lower mortality rates, decreased NEC and IVH, and decreased need for surfactant and mechanical ventilation therapy were seen only with exposure to a complete course of steroids (table 2). Complete steroid coverage was associated with significantly lower birth weight and smaller head circumference ($p = 0.035$ and $p = 0.046$, respectively), higher likelihood of CLD (OR 1.39, 95% CI 1.06 to 1.83, $p = 0.023$) and longer hospital stay (75.5 vs 73 days, $p = 0.002$). No steroid coverage was associated with reduced rates of systemic infection (31.3% vs 38.9%, $p = 0.015$) compared with complete coverage. Further analysis was performed according to subgroupings of none or <24 h exposure versus a complete course of steroids given >7 days prior to delivery. This revealed similar trends in terms of mortality and morbidities. A complete course of steroids given 48 h to >7 days prior to delivery significantly lowered mortality (OR 0.53, 95% CI 0.44 to 0.64, $p < 0.001$). This exposure group was also associated with lower likelihood of surfactant therapy, mechanical ventilation and IVH, but increased incidence of proven systemic infection and CLD and smaller anthropomorphic measurements (table 2).

Adjustment for confounding factors by multivariate logistic regression analysis revealed the risk of mortality to be significantly higher with incomplete or no steroid coverage (Adjusted OR 1.874, 95% CI 1.522 to 2.306; $p < 0.001$); this association continued to be significant within gestational age subgroups (table 2). Significant factors predictive of mortality included male gender, early gestational age (22–26 weeks) and small for gestational age (SGA). Hypertensive disease of pregnancy appeared to reduce mortality risk (adjusted OR 0.643, CI 95% 0.447 to 0.924, $p = 0.017$) (table 2).

Long-term neurodevelopmental outcomes

Overall, long-term neurodevelopmental outcomes were not significantly different between infants receiving no steroids compared with any steroid exposure (table 3). Any exposure to steroids was associated with decreased likelihood of moderate CP compared with no exposure (OR 0.39, 95% CI 0.18 to 0.84, $p = 0.041$). However, when the combined groups of no

Table 4 Multiple logistic regression model to determine independent factors associated with mortality among premature infants born <29 weeks

Variable	OR, 95% CI	p Value

In vitro fertilisation includes gamete intrafallopian transfer, zygote intrafallopian transfer, intracytoplasmic sperm injection, etc. Hyperovulation includes any hormone therapy used to stimulate ovulation.

Values are OR (95% CI). Infants who did not receive steroids and those with <24 h before delivery were set as referent group. Analysis was performed for whole 22–28 weeks cohort and then stratified for the two subgroups of 22–26 weeks and 27–28 weeks gestational age.

AGA, appropriate for gestational age; LGA, large for gestational age (>90th percentile); SGA, small for gestational age (<10th percentile).

steroids and less than 24 h was compared to the combined group of complete course or greater than 7 days, a 1.9% decrease in moderate CP was found but this did not reach statistical significance ($p = 0.078$). Multiple logistic regression analysis for factors predictive of adverse long-term outcomes revealed that antenatal steroids had no significant effect on long-term moderate/severe FD after adjustment for confounders (adjusted OR 1.056, 95% CI 0.785 to 1.420, $p = 0.720$). Other factors found to be significant for moderate/severe FD were male gender (adjusted OR 1.853, 95% CI 1.382 to 2.485, $p < 0.001$), 22–26 weeks gestational age (adjusted OR 2.365, 95% CI 1.774 to 3.151, $p < 0.001$) and SGA (adjusted OR 2.160, 95% CI 1.436 to 3.249, $p < 0.001$) (table 4).

Gestational age outcomes

Subgroup analysis of the cohort by gestational age was performed, excluding five infants born at 22 weeks that did not survive hospital discharge. A significant reduction in mortality was evident from 24 to 27 weeks gestational age with a complete course of antenatal steroids, compared with those who received none or an incomplete course (table 5). Decreased mortality in infants born at 23 weeks and 28 weeks was observed, but did not reach statistical significance ($p = 0.239$ and $p = 0.448$, respectively). Severe IVH was significantly lower at 24–28 weeks gestational age in infants receiving a complete course of antenatal steroids (table 5). CLD was more likely in infants receiving a complete course of steroids across all gestational ages, but this did not reach statistical significance, except at 24 weeks ($p = 0.039$) and 26 weeks gestational age ($p < 0.001$). No significant differences were observed between treatment groups for long-term neurodevelopmental outcomes (table 5).

DISCUSSION

It has previously been demonstrated that only a complete course of steroids confers survival benefit and reduction in IVH for

infants born 23–26 weeks; a benefit that persists even if administration of steroids is more than 7 days from delivery.²⁰ Our data, in line with existing literature, shows that only infants who received a full course of steroids more than 48 h prior to delivery obtained the benefits of steroids. These benefits were not gained by infants who received no steroids or an incomplete course. Our results add impetus to the argument for prompt commencement of antenatal steroids when premature delivery is likely, to maximise the likelihood of a full course of steroids being received prior to delivery.

Previous cohort studies showed that steroid exposure made no significant difference to rates of CLD, the need for respiratory support and length of hospital stay.^{3–7} By contrast, our study showed that full steroid exposure was associated with a reduction in the need for surfactant and mechanical ventilation. However, infants in this cohort that received a complete steroid course were more likely to record anthropomorphic measurements in the lower percentiles, increased rates of CLD and longer hospital stays.

Previous research demonstrates that steroid exposure is associated with less developmental delay at 1 and 3 years of follow-up^{21–22} and lower incidence of CP after steroid exposure.²² Our results showed that complete steroid exposure may be associated with a reduced likelihood of moderate CP in premature infants at 2–3 years of follow-up. However, we found no overall significant differences in long-term neurodevelopment with steroid exposure. However, because the number of neonates who received no steroids was small, this difference may not necessarily hold true if the numbers had been greater. With the significant survival and short-term morbidity that antenatal steroids provide, it is unlikely that a study would occur where a comparison of no steroids, as against steroid exposure, would occur in the current climate. However, future studies aimed at evaluating whether two doses of betamethasone (4 doses of dexamethasone) in 24 h confers the same benefit as 2 doses of betamethasone (4 doses of dexamethasone) after 48 h would be beneficial.

In utero inflammation is implicated as a risk factor for premature delivery.²³ In the presence of chorioamnionitis, the administration of a complete course of antenatal corticosteroids is associated with decreased risk of IVH and CP in premature infants.²⁴ We found lower rates of IVH and moderate CP with steroid coverage in our cohort study, consistent with previous studies.

The observed improvement in survival from 24 weeks to 27 weeks gestational age with complete steroid coverage, and the significant reduction in severe IVH from 24 weeks to 28 weeks, is consistent with the literature. Cohorts stratified for gestational age previously showed reduced mortality from 22 weeks to 27 weeks gestational age.^{7–8} Although mortality was not shown to be significantly reduced at 23 weeks gestational age with complete steroid exposure, the small sample of 23-week infants in our study may have been insufficient for measurement of a significant effect; it is possible that a survival advantage is still afforded by steroids at extremely premature ages.⁷

Strengths of our study include the fact that it was a geographically defined population-based cohort study, which means that results are unlikely to be biased by centre-based information. The standardised collection of data by the NICUs Data Collection and Follow-up Data Collection also ensured consistently collected data for the 6-year epoch. However, this study in itself is retrospective in nature. There were relatively small sample sizes for gestational ages of 22–25 weeks and missing parameters for 12% of the follow-up cohort included at long-term assessment. These limitations raise the possibility that

other significant effects of antenatal steroid exposure on long-term outcomes may not have been detected in our study population. Further analysis using on-going data collection could examine the cohort's long-term outcomes at 5 years and 10 years, determining the effects of antenatal steroid exposure on later learning and development.

This study demonstrates a clear benefit derived from steroid coverage across gestational ages. The clinical application of results from this large-scale cohort study pertains to preliminary counselling of parents of premature infants. In the context of decisions regarding intensive care treatment, the gestational age tables generated could be used in discussion of the likelihood of survival, perinatal complications and long-term FD given exposure to steroids. Furthermore, outcome data from such cohort studies could eventually be used to formulate survival prediction equations that include prenatally available parameters, such as steroid exposure.²⁵

CONCLUSIONS

Within this Australian cohort of extremely premature infants, there was significant improvement in hospital survival and reduced NEC and IVH with exposure to antenatal steroids. This advantage was afforded only by exposure to a complete steroid course. Significant survival benefit and decreased incidence of IVH was seen from 24 weeks to 28 weeks gestational age. Antenatal steroids were associated with a decreased risk of moderate CP. Long-term neurodevelopmental outcomes in premature infants at 2–3 years follow-up were not significantly affected by antenatal steroid exposure.
